In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

	Total (Volunteered and Elicited)		
Body System/ Adverse Reaction	Visken (pindolol) (N = 322) %	Active controls* (N = 188) %	Placebo (N = 78) %

* Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and non-thrombocytopenic purpura.

Gastrointenstinal: Mesenteric arterial thrombosis; ischemic colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

OVERDOSAGE
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

Excessive Bradycardia: administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure: digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

Hypotension: administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a $beta_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ≥ 80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 5 mg b.i.d. alone or in combination with other antihypertensive agents. An antihypertensive response usually occurs within the first week of treatment. Maximal response, however, may take as long as or occasionally longer than two weeks. If a satisfactory reduction in blood pressure does not occur within 3-4 weeks, the dose may be adjusted in increments of 10 mg per day at these intervals up to a maximum of 60 mg per day.

HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05).

For your most critical patients . . . external pacing buys time.

Physio Control's new LIFEPAK® 8 defibrillator/monitor with QUIK-PACE™ external pacing cassette safely paces a nonperfusing cardiac patient during the critical minutes needed to thread a transvenous pacing wire or administer drug therapy. This can mean the difference between life and death.

Demand pacing is initiated with impressive ease. Continuous current selection allows capture at the lowest necessary setting. When the patient is stabilized, decisions are made in a confident atmosphere. There's more time for exacting procedures.

Now you can monitor, defibrillate and externally pace with one integrated system. There's never been anything like it.

We're breaking new ground. The LIFEPAK 8 defibrillator/monitor with QUIK-PACE external pacing cassette has no competitors.

Physio-Control.
Defining the standard for the next generation of defibrillator/monitors.

Frequency of Pericardial Effusion as Determined by M-Mode Echocardiography in Acute Myocardial Infarction

KERRY KAPLAN, MD, RICHARD DAVISON, MD, MICHELE PARKER, RN, MS, JEAN PRZYBYLEK, RN, MS, AMY LIGHT, BS, DENNIS BRESNAHAN, MD, HILLEL RIBNER, MD, and JAMES V. TALANO, MD

A pericardial friction rub occurs in 6 to 16% of patients after acute myocardial infarction (AMI), but the incidence of pericardial effusion (PE) is not known. M-mode echocardiography was done 1, 3 and 5 days after AMI in 43 consecutive patients admitted within 24 hours of AMI, and PE was detected in 16 (37%). The PE was small in 7 patients, moderate in 6 and large in 3. A pericardial friction rub developed in 8 (19%), of whom only 4 had PE. Pleuritic chest pain diminished by sitting up and relieved by antiinflammatory agents developed in 12 (28%), of whom only 5 had PE. The peak creatine kinase level was significantly higher in patients with PE (1,769 ± 1,003 U) than in those without (1,181 ± 838 units). More patients with PE were in Killip classification II, III or IV (11 of 16 [69%] vs 9 of 27 [33%]). The presence of PE was not associated with age, site of AMI, development of Q waves, use of heparin or previous AMI. In conclusion, PE as detected by M-mode echocardiography is frequently present after AMI, and its presence is not closely associated with the occurrence of a pericardial friction rub or typical pericardial pain.

(Am J Cardiol 1985;55:335–337)

A pericardial friction rub occurs in 6 to 16% of patients after an acute myocardial infarction (AMI).[1–6] These patients frequently have pleuritic chest pain, lessened by sitting up and relieved by antiinflammatory agents; however, the incidence of pericardial effusion (PE) is unknown. The objective of this study is to determine the incidence of echocardiographically detected PE after AMI.

Methods

Patient selection: Patients admitted to the coronary care unit at Northwestern Memorial Hospital within 24 hours of a suspected AMI were considered eligible for inclusion in this study if they did not have a concomitant condition associated with PE or pericarditis. One hundred sixty-two patients were screened for inclusion in the study and 86 were excluded for the following reasons: AMI (28 patients) or cardiac surgery (7) within 6 months, cardiogenic shock (5), chronic renal failure (with BUN >50 mg/dl, creatine >4 mg/dl) (12), metastatic disease (8), rheumatoid arthritis (2), systemic lupus erythematosus (1), progressive systemic sclerosis (1), ankylosing spondylitis (1), chronic congestive heart failure with pleural effusions (9), or refusal of patient (10) or attending (2) to give consent. Thirty-one of the 86 excluded patients were later diagnosed as having AMI.

Seventy-six patients consented to the study. In 3 patients a technically satisfactory echocardiogram could not be obtained on the first day, and these patients were excluded from further analysis. Thirty patients had initial echocardiograms performed and were later found not to have had AMI. This report is based on the remaining 43 patients who had serial M-mode echocardiography after an AMI.

Methods: M-mode echocardiography was performed with either a Smith Kline Ekoline or Irex System II ultrasonoscope with a 2.25-MHz transducer. Standard technique was used with the transducer placed in the parasternal position. A switch-gain ("damping") mechanism was used to evaluate the pericardial space.

The initial echocardiogram was performed within 24 hours of admission for a suspected AMI; echocardiograms were repeated from the same chest position on the third and fifth day. In patients who had PE, echocardiograms were repeated 2 times per week until the effusion resolved or the patient was discharged from the hospital.

Clinical evaluation: AMI was diagnosed by the association of a compatible clinical presentation with either creatine kinase-MB ≥5% on 2 determinations or a positive technetium pyrophosphate myocardial scan. Myocardial infarctions were then classified as either Q wave with the appearance of 2 or

PE = pericardial effusion.

more Q waves of at least 0.04 second or non-Q wave with the appearance of 1 mm or more of ST depression or symmetric T-wave inversions persisting for 3 days or longer.

A clinical diagnosis of pericarditis was made either by auscultation of a pericardial friction rub or by the presence of classic pericardial chest pain, lessened by sitting up and relieved by antiinflammatory agents. Patients were evaluated at least twice daily by a cardiologist. Special attention was directed to the detection of pericardial friction rubs and evaluation of chest pain for characteristics suggestive of pericarditis. This study was approved by the Northwestern University Institutional Review Board and the Northwestern Memorial Hospital Research Committee.

Echocardiographic evaluation: Presence of PE was assessed using the method described by Horowitz et al.[7] The presence of a C2 or D pattern was considered indicative of PE. Two echocardiographers independently analyzed the first 3 echocardiograms in each series without knowledge of the patient's identity or clinical course. On the initial analysis there was disagreement on the presence of PE in 3 patients; these differences were resolved by a concurrent review of these echocardiograms. The amount of PE was estimated as small, moderate or large using standard techniques.[8]

Data analysis: Differences in proportions of categorical variables were tested for significance by the chi-square analysis with Yates continuity correction. For continuous variables, differences were tested for significance by the *t* test for unpaired data or the Wilcoxon rank-sum test. Statistical significance was considered at the $p < 0.05$ level. Values are expressed as mean ± standard deviation.

Results

Patient characteristics (Table I): Forty-three patients were entered into the study. The average age was 58 ± 10 years. Thirty-three of the patients had Q-wave AMI. Seven patients had non-Q-wave AMI. In 3 patients the presence of an intraventricular conduction disturbance made classification unreliable. The site of AMI was anterior in 14 patients, inferior in 23 and indeterminate in 6 (3 with conduction disturbances and 3 with lateral T-wave changes). Fourteen patients received subcutaneous heparin, 5,000 U twice daily. Twelve patients had had a previous AMI. Twelve patients (28%) had typical pericardial chest pain; in 8 of these 12 patients a pericardial friction rub was detected.

Pericardial effusion (Table I): PE was visualized by echocardiography in 16 patients. In 6 it was identified within 24 hours of the onset of chest pain. It was first detected on the third day in 6 others and the fifth day in 4. Serial echocardiograms indicated that no PE resolved completely before hospital discharge. The maximal size of the PE was estimated as small in 7 patients, moderate in 6 and large in 3.

Patients with PE had a higher peak creatine kinase level (1,769 ± 1,003) than those without (1,181 ± 838). More patients with PE were in Killip classification II, III or IV (11 of 16 [69%] vs 9 of 27 [33%]). There was a greater frequency of PE among women (10 of 16) than men (6 of 27). The age, weight, site of infarction, development of Q waves, history of AMI or use of heparin were not associated with the presence of PE.

There was not a close correlation between echocardiographically detected PE and pericardial chest pain. Of the 12 patients with pericardial pain, only 5 (42%) had PE and 11 patients with PE did not have pain. Likewise, there was not a significant association between the presence of a pericardial friction rub and PE (4 had both, 23 neither, 4 a rub without PE and 12 a PE without a rub). PE that was detected within the first 24 hours of an AMI could be unrelated to the acute event. In fact, only 1 of 6 patients with an early PE had typical chest pain with a rub. However, if these early PE are reclassified as no PE, there is still not a significant association between clinical pericarditis and PE.

Discussion

M-mode echocardiography is the procedure of choice for the detection of PE because it is accurate and noninvasive.[10,11] Effusions as small as 15 ml may be detected by M-mode echocardiography[7]; however, adipose tissue may cause a posterior echo-free space indistinguishable from PE.[12]

The incidence of early pericarditis after AMI has been variably reported as between 6 and 16% when diagnosed by the presence of a pericardial friction rub.[1–6] Pericardial chest pain suggestive of pericarditis was found in 28% of our patients, whereas 19% had pericardial friction rubs. A recent autopsy study of 85 patients who died within 6 months of an AMI found that 40% had pericarditis.[13]

Some investigators have stated that a detectable PE is rare after AMI.[1,4,14,15] Lichstein et al[1] reported that 6 patients with pericarditis soon after an AMI had echocardiograms that did not show significant PE. However, Kossowsky et al[15] reported 4 patients with pericardial chest pain who had angiographically documented PE within 2 weeks of an AMI; and in an autopsy series reported by Roeske et al,[13] 18% of patients had a PE. In a recent study by Wunderink,[16] M-mode echocardiography was done within 72 hours in 90 patients with

AMI and a PE was detected in only 5. The marked discrepancy in results is probably a reflection of differences in study design. In the present study 3 echocardiograms were performed on each patient by the same technician. In Wunderink's study each patient received a single echocardiogram that was done by 1 of 6 technicians.

A previous study by Markiewicz et al[17] showed no association between the presence of a pericardial friction rub and the amount of pericardial fluid detected by echocardiography. They describe 6 subjects with a typical clinical presentation of pericarditis, including a pericardial friction rub and no abnormal findings on M-mode echocardiography. Our results confirm that after AMI, chest pain suggestive of pericarditis is often not associated with an echocardiographically detected PE.

We conclude that PE as detected by M-mode echocardiography is frequently present after AMI, and its presence is not closely associated with the occurrence of a pericardial friction rub or typical pericardial pain.

Contractile Properties of the Left Ventricle with Aneurysm

STEPHEN ARVAN, MD, and PEDRO BADILLO, MD

Twenty-five patients with an anterior wall acute myocardial infarction (AMI) were studied by 2-dimensional echocardiography (2-D echo) 3 to 5 days after the onset of chest pain, and serially over 3 to 24 months to determine if a particular pattern of contractility may predispose to left ventricular (LV) aneurysm formation. No subject had a prior AMI. In 8 subjects LV aneurysm eventually developed (group I), usually within 2 to 4 weeks of AMI; in 17 patients LV aneurysm did not develop (group II). Percent fractional shortening of the basal and midventricular segments was significantly better in group I subjects than in group II subjects (29 ± 2% vs 20 ± 2%, p <0.01, respectively, for the basal segment, and 23 ± 1% vs 17 ± 2%, p <0.02, respectively, for the midventricular segment). Infarct size as determined by peak creatine kinase isoenzyme levels was large in both groups, and there was no statistically significant difference between their mean values (2,099 ± 620 IU vs 1,334 ± 249 IU for groups I and II, respectively). Severe asynergy of the infarcted myocardium was present in all group I subjects and in 9 of 17 group II subjects on the initial 2-dimensional echocardiographic study. These results indicate that LV aneurysm formation depends on a critical imbalance of myocardial forces where strong LV segments cause bulging of weakened ones. (Am J Cardiol 1985;55:338–341)

Why left ventricular (LV) aneurysm develops in some patients after an anterior wall acute myocardial infarction (AMI) and not in others has never been adequately explained. Factors such as a large transmural AMI[1,2] and first AMI[3] have been associated with LV aneurysm formation, but neither condition provides a mechanistic concept for its development. Recent studies suggest that early changes in the shape of the ventricle as a result of "expansion" of freshly necrotic myocardium may be the geometric precondition necessary for its eventual development[4] Hemodynamic factors may play a major role in the pathogenesis of such post infarction topographic distortion. The LV contractile properties were therefore analyzed by 2-dimensional echocardiography (2-D echo) to examine specific changes that may help to explain the evolution of LV aneurysm.

Methods

Patients: Thirty-five consecutive patients admitted to the coronary care unit with the first episode of an anterior wall AMI were selected for this study. Two-dimensional echocardiograms were performed within 3 to 5 days after admission and then serially over several months after discharge. In 3 patients 2-D echo was technically difficult to perform, and these patients were excluded from the study; 7 patients were lost to follow-up. The total study population, therefore, consisted of 25 patients. Group I consisted of 8 LV aneurysm patients, 7 men and 1 woman, aged 64 ± 4 years (range 36 to 75), who were followed for 3 to 24 months (mean 10). Group II included 17 patients, 14 men and 3 women, aged 57 ± 3 years (range 32 to 76), in whom LV aneurysm did not develop after the first episode of an anterior wall AMI. The follow-up interval for group II was 3 to 12 months (mean 9). Three subjects in Group I (38%) and 7 in Group II (41%) had a history of hypertension.

Two-dimensional echocardiography: Two-dimensional echo was performed with a Varian 3000R phased-array ultrasonograph using a wide-angle (80°), 2.25-MHz transducer. A standard cross-sectional echocardiographic study was obtained in which the LV long-axis, multiple short-axis views, and apical views of the left ventricle were imaged. Abnormal wall motion was graded as akinetic, dyskinetic or severely hypokinetic only if more than 50% of the involved segment showed the abnormality.

Regional performance of the LV myocardium was analyzed in the apical 4-chamber view. After the transducer was angulated to image the greatest diameter of the left ventricle, the LV cavity was subdivided in a cephalocaudad direction into approximately equal thirds (Fig. 1). The reference plane for the basal segment was at an area just above the posterior aortic anulus and atrioventricular ring. For the midventricular plane, the reference point was at the region of the anterolateral papillary muscle and for the apical plane, the reference position was at a point equidistant between the anterolateral papillary muscle and the LV apex. Percent fractional shortening (%FS) of the minor axis of the base, midventricular and apical segments was determined by dividing the difference between

From the Division of Cardiology, University of Pittsburgh, and Montefiore Hospital, Pittsburgh, Pennsylvania. Manuscript received July 25, 1984; revised manuscript received October 8, 1984, accepted October 9, 1984.

Address for reprints: Stephen Arvan, MD, Montefiore Hospital, 3459 Fifth Avenue, Pittsburgh, Pennsylvania 15213.

the end-diastolic length (EDL) at the onset of the electrocardiographic R wave, and the end-systolic length (ESL), taken at the time of least separation of the septum and LV lateral wall, by the end-diastolic value (FS = EDL − ESL/EDL × 100). Distances were measured with an off-line computerized light pen, and %FS measurements were recorded after averaging the results of 3 separate cardiac cycles.

The diagnosis of an LV aneurysm was made on the apical 4-chamber view or the apical 2-chamber view of the left ventricle if there was persistent bulging of a thinned area of the LV myocardium in systole and diastole.[5,6]

Cardiac isoenzymes: Total creatine kinase levels as well as MB fractions were measured on admission and in 3 additional sequential plasma samples taken 8, 16 and 24 hours after the onset of chest pain, and then once every 24 hours until the levels returned to normal. The creatine kinase-MB isoenzyme was separated by the ion exchange column chromatography technique described by Mercer.[7] The normal range is 15 to 150 IU. A creatine kinase-MB level of greater than 2% when total creatine kinase activity is over 150 IU or a creatine kinase-MB value of greater than 3 IU when the creatine kinase is less than 150 IU was considered positive for AMI.

Interobserver variability: Reproducibility of %FS calculations of the basal, mid and apical segments was assessed by determining the percent difference from the average of duplicate measurements from 2 observers. The mean percent difference was calculated by averaging the absolute percent difference for the 25 subjects studied. Linear regression analysis was used to indicate the variability of the data about the identity line.

Statistics: Values for the echocardiographic variables were expressed as the mean ± standard error of the mean. Comparison of values in the various clinical groups were made with the unpaired Student *t* test. Changes were considered significant at p values <0.05.

Results

Percent FS values of the basal, mid and apical regions soon after an AMI and on follow-up examination are illustrated in Tables I and II. Basal and midventricular %FS were significantly better in group I than in group II patients ($p < 0.01$, and < 0.02, respectively) early after an AMI. Apical %FS was reduced equally in both groups. In the late follow-up period, basal segmental contractility remained significantly better in group I patients ($p < 0.01$), whereas the midventricular segments appeared equal and the apical region became significantly worse in group I than group II patients ($p < 0.001$).

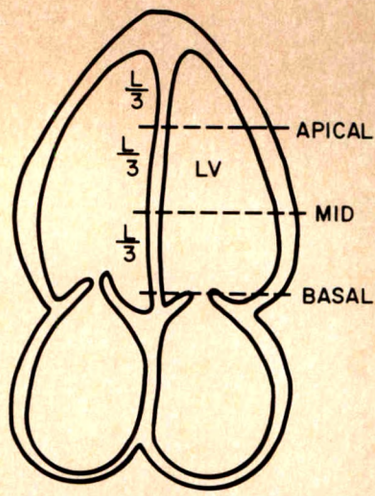

FIGURE 1. Regional contractility was measured by calculating percent fractional shortening at the base, midventricle and apex by dividing the major axis of the left ventricle (LV) into thirds starting at the base. L = long axis.

Nine subjects in group II had 1 or more segments that were dyskinetic in the apical 4- or 2-chamber view. Percent FS of the basal and midventricular segments was still better in group I than in group II patients with dyskinetic wall motion abnormalities (29 ± 2% vs 21 ± 2%, respectively, for the basal segment [$p < 0.02$] and 23 ± 1% vs 15 ± 2%, respectively, for the midventricular segment [$p < 0.01$]). Apical %FS values were not significantly different in the 2 groups (7 ± 2% vs 8 ± 2%, respectively).

Two-dimensional echocardiograms from a patient in group I in whom aneurysm developed are shown in Figure 2. One patient had a recurrent anterior wall AMI before a second study. In group II, a second anterior wall AMI developed in 3 patients and an inferior wall AMI

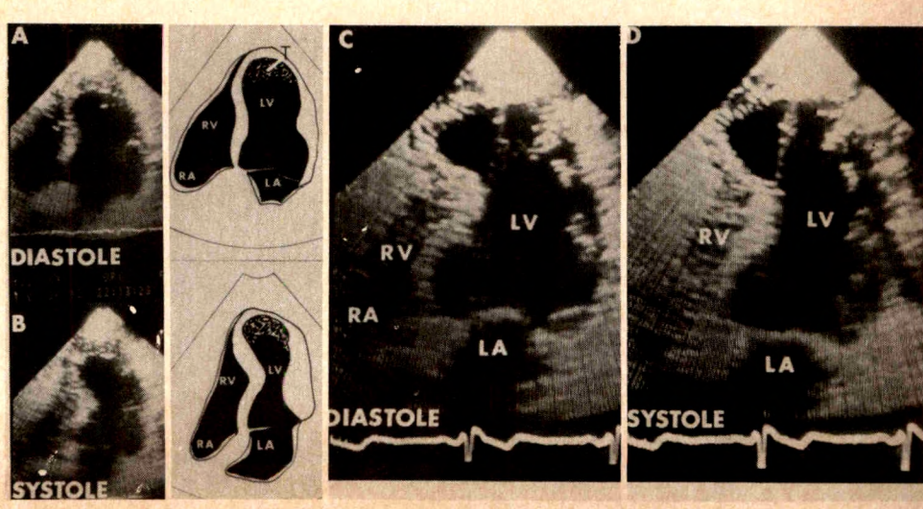

FIGURE 2. A and **B**, 2-dimensional echocardiogram shows slight infarct expansion at the apex and well preserved contractility of the basal and midventricular segments. **C** and **D**, 8 weeks after acute myocardial infarction, septal apical aneurysm developed. Contractility of the left ventricular base and midventricle is still well preserved. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle; T = thrombus.

%FS = percent fractional shortening; LV = left ventricle; SEM = standard error of the mean.

developed in 1 patient, with dramatic changes in his %FS (patient RJ).

The peak creatine kinase levels for group I subjects was 2,099 ± 620 IU; that for group II was 1,334 ± 249 IU. There was no statistically significant difference between the 2 groups, although 2 subjects in group II had a moderate to small AMI as judged by peak creatine kinase levels less than 350 IU.

Interobserver variability: Interobserver reproducibility was determined for FS values of the basal, mid and apical segments. The mean percent difference for the basal segment was 10%, for the midsegment 10% and for the apex 13%. The correlation coefficients were 0.94, 0.91, and 0.96, respectively.

Discussion

In 8 of 25 patients in the current investigation, LV aneurysm developed after anterior AMI. Percent FS values of the minor LV axis at the base, midventricle and apex showed that contractility was better in the basal and midventricular regions in these patients than in those in whom LV aneurysm did not develop. These changes were present on the initial 2-D echocardiograms performed 3 to 5 days after admission of an AMI, and on serial echocardiograms performed over 3 to 2 months. On the initial 2-D echocardiogram, 5 patients had no evidence of geometric distortion, but 3 had evidence of infarct expansion without a distinct aneurysm. On follow-up examination 7 of 8 patients had an LV aneurysm between the second and fourth week after AMI, and in 1 patient the aneurysm became apparent only at the eighth week after AMI. In group II, %FS remained similar or improved between studies among patients who did not have an intervening AMI. Midventricular and apical segments showed the most improvement.

The mechanism whereby augmented segmental LV performance leads to LV aneurysm formation is likely related to the influence of changes in wall stress. Strong contraction of the basal and, at times, the midventricular segments may generate enough LV systolic pressure to produce stretching and loss of geometric integrity of the weakened anteroapical segments. A similar mechanism had been proposed for dyskinetic wall motion abnormalities after ischemia or infarction.[9] In the absence of forceful contraction of the surrounding

Abbreviations as in Table I.

myocardium, infarcted regions may maintain a normal LV contour because hemodynamic forces are insufficient to produce a critical increase in systolic pressure. This may explain the observation that an aneurysm tends to develop after a first AMI[3] when the uninvolved myocardium can still compensate for the loss of contractility of the infarcted myocardium.

Extensive myocardial necrosis has been cited as an important precursor in the development of an LV aneurysm.[3,8,10,11] In the present study, infarct size, as determined by peak creatine kinase levels, was large in patients in groups I and II. Mean values exceeded 1,300 IU in both instances. Statistically, there was no significant difference in peak creatine kinase values between the study groups. These results suggest that although LV aneurysm occurs after a large AMI, it is not the infarct size alone that determines its formation; other conditions must be present.

Initial wall motion abnormalities as detected by 2-D echo were more severe in group I than in group II subjects. This was particularly true for the LV apex, an area that was invariably involved either completely or partly by the LV aneurysm. In the former group, all patients showed dyskinesia or extensive akinesia of the apex, while in the latter group 8 of 17 patients demonstrated either hypokinesia or normal motion of the apex. Severe asynergy on 2-D echo correlates well with the presence of a transmural infarct.[5,12] A distinguishing feature on 2-D echo, therefore, was evidence of a transmural AMI involving the apex in group I and a lower incidence of the same pattern in group II. Nine of 17 patients in group II, however, had severe asynergy at the apex, yet they did not progress to aneurysm formation. On comparing %FS values of this subgroup with that for group I, there was still significantly greater %FS at the base in group I than in group II. Therefore, the presence of a transmural AMI alone does not explain LV aneurysm formation, but is one of the multifactoral conditions necessary for its development.

Limitations of the study: Interobserver variation in measuring segmental %FS was greatest for the apex (13%). The correlation coefficient was good ($r = 0.96$), however, indicating that there was concordance in interpreting the trend of contractility for the apical segment. Although reproducibility of apical %FS measurements appear low, the results may be misleading. Frequently the absolute FS values were small numbers and a difference of 1 or 2% between observers introduced a significant degree of variability.

The incidence of LV aneurysm after AMI could not be stated in this study because several patients were lost to follow-up or could not be included because of technical difficulty in performing 2-D echo. Although overall incidence of an LV aneurysm has been reported to vary between 4 to 20% after an AMI[13–15] by morphologic studies, the noninvasive estimate may differ since only the sickest patients are reported at autopsy.

Finally, %FS is a semiquantitative estimate of the state of contractility[16] and the results are influenced by angulation of the transducer and rotation of the heart. Perhaps an alternative method would be the assesment of wall thickening, which is uninfluenced by these factors.[17,18] Unfortunately, the epicardium is poorly defined around the full circumference of the left ventricle, particularly the lateral ventricular wall and the apical septal region. For this reason, we confined our measurements to the endocardial surface by calculating %FS along the minor axis of 3 identifiable segments.

Assessment of Hemodynamic Significance of Isolated Stenoses of the Left Anterior Descending Coronary Artery Using Thallium-201 Myocardial Scintigraphy

VICTOR KALFF, MB BS, MICHAEL J. KELLY, MB BS, ALAN SOWARD, MB BS, RICHARD W. HARPER, MB BS, PHILIP J. CURRIE, MB BS, YEAN L. LIM, MB BS, PhD, and AUBREY PITT, MD

This study tests the hypothesis that the results of stress thallium-201 myocardial perfusion scans (Tl-201) are related to the mean transstenotic pressure gradient of coronary stenoses independent of the percent luminal diameter narrowing seen at angiography. The 22 study patients (20 men, 2 women, mean age 47 years, range 30 to 62) had no previous myocardial infarction. Each underwent a symptom-limited, erect bicycle Tl-201 test off antianginal therapy, shortly before percutaneous transluminal coronary angioplasty for isolated left anterior descending coronary artery stenosis. The percent narrowing, mean gradient at percutaneous transluminal coronary angioplasty and presence of a visually apparent Tl-201 defect were independently evaluated and results compared. All 4 patients with 90% or greater diameter narrowing had positive Tl-201 responses, and the mean gradient was 72 ± 11 mm Hg. Among the 18 patients with less than 90% diameter narrowing, the mean gradient was higher ($p < 0.001$) in the 11 with a positive Tl-201 (63 ± 15 mm Hg) than in the 7 with a negative Tl-201 (33 ± 20 mm Hg), but their percen narrowing did not differ significantly (72 ± 14% vs 66 ± 19%). Multiple regression analysis showe that the presence of a Tl-201 defect was a strong ($p = 0.003$) and percent narrowing ($p = 0.048$) a weak independent predictor for gradient. When the mean gradient was normalized for the prestenotic pressure, both percent narrowing ($p = 0.003$) and Tl-20 defects ($p = 0.006$) were significant independen predictors. Other variables, including age, locatio and length of stenosis, exercise electrocardio graphic ST-segment changes, hemodynamics workload and chest pain, did not enter the equation as significant independent predictors of gradient Therefore, Tl-201 adds valid information on th hemodynamic significance of a stenosis indepen dent of percent luminal diameter narrowing; this ma be of most value when percent narrowing is les than 90% and the clinical significance of a coronar stenosis is uncertain.

(Am J Cardiol 1985;55:342–346

In patients with myocardial ischemia, the degree of stenosis that is found at coronary angiography has traditionally been considered the most important variable against which all other tests attempting to assess coronary artery disease (CAD) have been compared.[1] However, angiography has limitations. Patients with angiographically similar degrees of stenosis have a wide range of coronary blood flow disturbance[2] and symptoms. Although routine measurement of absolute cor onary blood flow is not possible in patients, stress-in duced relative coronary blood flow changes can b examined using thallium-201 myocardial perfusio (Tl-201) scintigraphy.[3] However, in previous studie the scan findings were usually interpreted on the basi of the findings at coronary angiography without al lowing for the possibility that when these 2 tests yiel discrepant results, it may be because scintigraph produces a more valid reflection of the hemodynami significance of CAD than angiography.

Because it gives a physiologic measurement of th hemodynamic severity of a coronary stenosis, mea surement of the transstenotic pressure gradient durin percutaneous transluminal coronary angioplast

(PTCA)[4] provides a new chance to test the hypothesis that the results of Tl-201 scanning may add to standard coronary angiography in determining the true hemodynamic significance of individual stenoses. This question is particularly relevant when angiographic narrowing appears only moderate and the stenosis is of uncertain clinical significance. We have tested this hypothesis by comparing the results of coronary angiography, mean transstenotic gradients and exercise Tl-201 scanning in patients with isolated left anterior descending coronary artery (LAD) CAD undergoing PTCA.

Methods

Patients: All study patients underwent diagnostic coronary angiography for chest pain, and then stress Tl-201 scintigraphy followed by PTCA. The scan results did not influence the decision to proceed to PTCA. The study population comprised consecutive patients with (1) 1-vessel CAD of the LAD, (2) no electrocardiographic evidence, cardiac enzyme increase or history of myocardial infarction, (3) the ability to undergo erect bicycle exercise to more than 200 kpm/min or angina, and (4) successful pressure measurements at PTCA. Two women and 20 men fulfilled all these criteria. The mean age of these patients was 47 years (range 30 to 62).

Exercise thallium-201 scintigraphy: Beta-blocker and calcium antagonist therapy was withheld for more than 48 hours and nitrates more than 12 hours before a symptom-limited Tl-201 stress test using a continuous 3-minute/stage graded erect bicycle exercise protocol. Continuous electrocardiographic monitoring was performed throughout, with heart rate and 12-lead electrocardiogram recorded each minute, and blood pressure at 3-minute intervals. Two minutes before ceasing exercise, 1.5 to 2.0 mCi of Tl-201 was injected intravenously. Immediately after exercise, the patient was placed supine. After 3 minutes the precordial leads were removed and Tl-201 data were acquired on a Searle LEM gamma camera using a dual-energy window and high-resolution, low-energy collimator. Images were acquired in the 45° and 60° left anterior oblique, anterior and left lateral decubitus projections on photographic transparencies and as a 128 × 128 matrix image on a dedicated minicomputer (Digital Equipment Corp. PDP 11/34). Imaging duration for the postexercise and 2- to 3-hour delayed images was the time required to collect 300,000 counts for the first view.

Before PTCA, the Tl-201 transparencies and 20% thresholded computer images were qualitatively interpreted, using Dunn's criteria of normal or abnormal,[5] by 2 independent, experienced readers who had no knowledge of each patient's CAD status. If the scans were abnormal, the location of the defect was allotted to a coronary artery territory[6] and its severity graded qualitatively on a 4-point scale.

Angiographic and hemodynamic assessment at PTCA: PTCA was performed using the transfemoral approach.[4] In all patients this was performed within 48 hours of the Tl-201 stress test, except in 1 patient whose condition was clinically stable; this patient had PTCA 2 weeks later. Patients received premedication with sublingual nifedipine and received a continuous intravenous infusion of glyceryl trinitrate (50 to 100 μg/min) during PTCA. Multiple view coronary angiography of the LAD was performed using the Judkins technique. A 3.5 Fr Grüntzig balloon dilatation catheter was then passed across the lesion and mean arterial pressures recorded proximal and distal to the stenosis. Multiple balloon inflations were performed until no further reduction in lesion gradient could be achieved. Repeat pressures and gradients were then recorded, and a repeat multiview angiogram was taken.

To allow for variation in the mean transstenotic gradient resulting from changes in mean aortic pressures,[7] the mean gradient was divided by mean prestenotic pressure and this ratio defined as the normalized gradient. The stenosis before and after PTCA was measured from high-contrast, magnified cineagiographic images. The LAD was traced out, the diameter proximal and distal to the stenosis, and at the stenosis itself, measured in 2 views with Vernier calipers and the mean percentage luminal diameter narrowing (henceforth referred to as percent narrowing) was determined. The stenosis was considered to be proximal if it was between the origin of the LAD and its first septal perforator or first diagonal branch; middle if it was between these branches and the second diagonal branch; and distal if it was beyond the latter branch. Lesion length was estimated on a 4-point scale. The presence or absence of collaterals was also assessed visually.

Statistical analysis: Quantitative results are expressed as mean ± 1 standard deviation (range). Stepwise linear regression analysis was performed for assessment of predictors of transstenotic gradient. Univariate predictors of gradient were assessed with either Pearson's correlation coefficient, *t* tests or analysis of variance where appropriate. The standard error of the estimate (SEE) was defined as 1 standard deviation of the predictive error.

Results

At coronary angiography, 11 patients had a proximal and 11 a mid-LAD stenosis. Only 1 patient had collateral vessels. Maximal exercise-induced heart rate was 155 ± 24 beats/min (range 105 to 190); systolic blood pressure 193 ± 25 mm Hg (range 150 to 230), work load 802 ± 310 kpm/min (range 200 to 1,500); and exercise time 13 ± 4 minutes (range 2 to 20). Fifteen patients had a positive Tl-201 response, including the 8 with a positive electrocardiographic stress test (1 mm or more of ST-segment depression). Of the 11 with chest pain during exercise, 2 (workloads greater than 1,000 kpm/min, peak heart rates greater than 145 beats/min) had a normal Tl-201 response. All patients with an abnormal Tl-201 scan had defects corresponding only to the LAD territory.[6] There was no interobserver disagreement over the normality or abnormality of a Tl-201 study.

The mean arterial pressure at the time of transstenotic pressure gradient measurement was 90 ± 13 mm Hg (range 80 to 120). At univariate analysis, a weak but significant correlation ($r = 0.52$, $p < 0.05$, SEE = 19) was found between percent narrowing and mean transstenotic pressure gradient measured before PTCA; a slightly better correlation ($r = 0.64$, $p < 0.005$) was observed between percent narrowing and normalized gradient (Fig. 1). After PTCA, the mean gradient decreased from 55 ± 22 mm Hg (range 0 to 80) to 21 ± 21 mm Hg (range 0 to 39), and percent narrowing from 75 ± 17% (range 33 to 99%) to 27 ± 21% (range 0 to 58%). Combining the pre- and post-PTCA data widened the range of pressure gradients and percent narrowing, thus making the relation between gradient and percent narrowing ($r = 0.82$, $p < 0.0001$, SEE = 16) much more apparent.

Analysis of variance found no association between gradient and qualitative Tl-201 abnormality score in patients with a Tl-201 perfusion defect. Therefore, in all figures, Tl-201 scan results are shown as either pos-

TABLE I Multiple Regression Analysis

	Dependent Variables			
	Absolute Gradient		Normalized Gradient	
	F Value	p Value	F Value	p Value
Independently predictive variables

itive (abnormal perfusion defect) or negative (no perfusion defect). Figure 2 depicts the relation between Tl-201 scanning and absolute (Fig. 2A) or normalized transstenotic gradient (Fig. 2B). Those with a negative Tl-201 scan had a mean absolute gradient of 33 ± 20 (range 0 to 55) mm Hg and a normalized gradient of 0.40 ± 0.24 (0 to 0.60); those with positive scans had an absolute gradient of 65 ± 14 (40 to 80) mm Hg and a normalized gradient of 0.70 ± 11 (range 0.51 to 0.84).

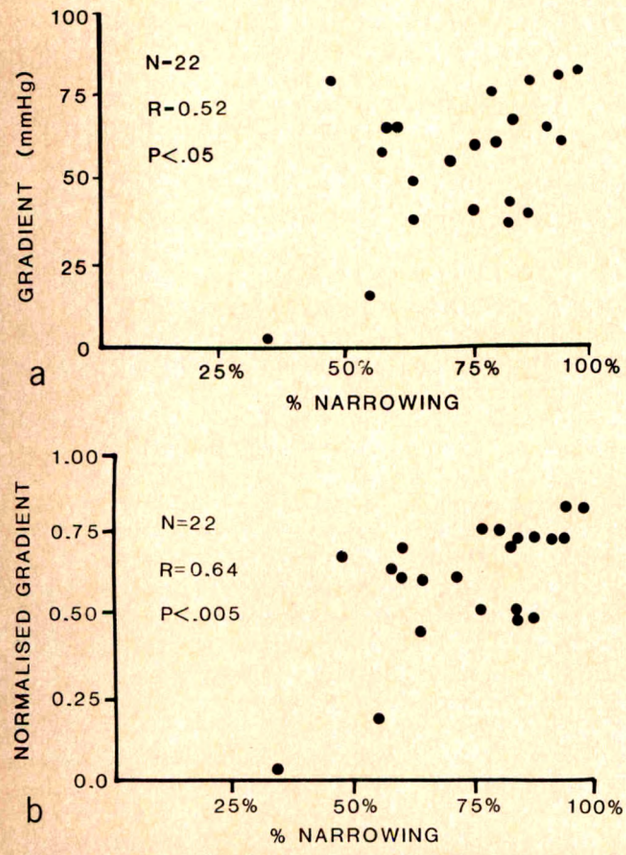

FIGURE 1. The relation between percent luminal diameter narrowing and (**a**) mean gradient and (**b**) normalized transstenotic pressure gradients. The correlation is slightly better for normalized than for absolute gradient, although in both cases there is a wide scatter of results. The normalized gradient is calculated as the mean transstenotic gradient/mean prestenotic pressure.

Results of multivariate analysis are summarized in Table I. With either mean transstenotic gradient or normalized gradient as the dependent variable, only Tl-201 results and percent narrowing were significant independent predictors, and percent narrowing was a better predictor of normalized than absolute gradient.

Figure 3 shows the relation between percent narrowing, transstenotic gradient and a positive or negative Tl-201 study. In the 18 patients with percent narrowing less than 90%, the mean gradient was significantly higher ($p < 0.001$) in those with a positive (63 ± 15 mm Hg) than those with a negative Tl-201 scan (33 ± 20 mm Hg), while their mean percent narrowing did not differ significantly (72 ± 14% vs 66 ± 19%).

Discussion

This study has shown that for a given degree of angiographically defined coronary artery stenosis, exercise Tl-201 myocardial perfusion scintigraphy can demonstrate a variable ability to augment coronary blood flow with stress, and that this variability is related to another hemodynamic measurement of lesion severity: the transstenotic pressure gradient.

Coronary angiography has the major role in assessing patients presenting with chest pain suggestive of myocardial ischemia. Nevertheless, it has important limitations. It may underestimate the significance of a stenosis if there is surrounding diffuse narrowing[8] or spasm during physical or emotional stress.[9] Overestimation is likely if spasm occurs during angiography. Significant interobserver variability in visual interpretation of lesions[10] has led to computer-assisted quantitation of absolute diameter narrowing.[11] However, a universally acceptable system is not available because of problems with variation in vessel caliber,[12] irregular, eccentric or serial lesions, contrast streaming through a lesion and effects of collateral vessels.[9,13] These difficulties have led to a search for supplementary methods of assessing the significance of CAD.

One such method, measurement of transstenotic pressure gradient, was used in this study as an indicator

of flow disturbances because it can be readily performed during PTCA.[4] This measurement has its own limitations in that it is necessarily invasive and overestimating true gradient by further occlusion of the stenosis by the catheter itself.[14] However, this overestimation, is relatively systematic,[14] and thus does not alter our overall findings. Because lesion gradient may change with varying aortic pressures,[7] a normalized gradient measurement was also used. This showed that Tl-201 scintigraphy still provides significant independent information about lesion hemodynamics.

Despite its deficiencies, transstenotic gradient correlates well with other physiologic measurements of coronary blood flow disturbance such as coronary flow reserve,[15] thought to characterize more truly the functional significance of a coronary lesion than percent stenosis.[2,16] White et al[2] directly measured coronary flow reserve in a group of patients undergoing coronary artery bypass surgery and found that it correlated poorly with angiographically determined percent stenosis. They questioned the use of angiographic measurements alone to determine the need for surgery. Our results agree with theirs in that the range of hemodynamic abnormality for a given percent stenosis was large despite a significant correlation between percent stenosis and gradient. More recently, Harrison et al[12] found that the absolute cross-sectional area of a stenosis, a variable that could not be measured in our study, correlated with coronary flow reserve better than did percent stenosis. Their data provide further evidence that the diffuse nature of CAD limits the usefulness of percent stenosis in determining the true significance of coronary narrowings.[8] However, absolute cross-sectional area measurement is itself of limited clinical value in that it requires sophisticated analysis that can only be meaningfully interpreted in vessels if their normal caliber is known, an uncommon situation. Furthermore, it cannot reflect the hemodynamic effects of the exercise-induced spasm that occurs in many patients.[9]

Tl-201 scanning was used in this study because it is minimally invasive and its myocardial uptake is linear over a wide range of coronary blood flow rates.[3] It is applicable to vessels of varying caliber,[12] and can reflect the effects of exercise induced spasm and collateralization.[9] Our finding that abnormal Tl-201 scans were associated with higher transstenotic pressure gradients

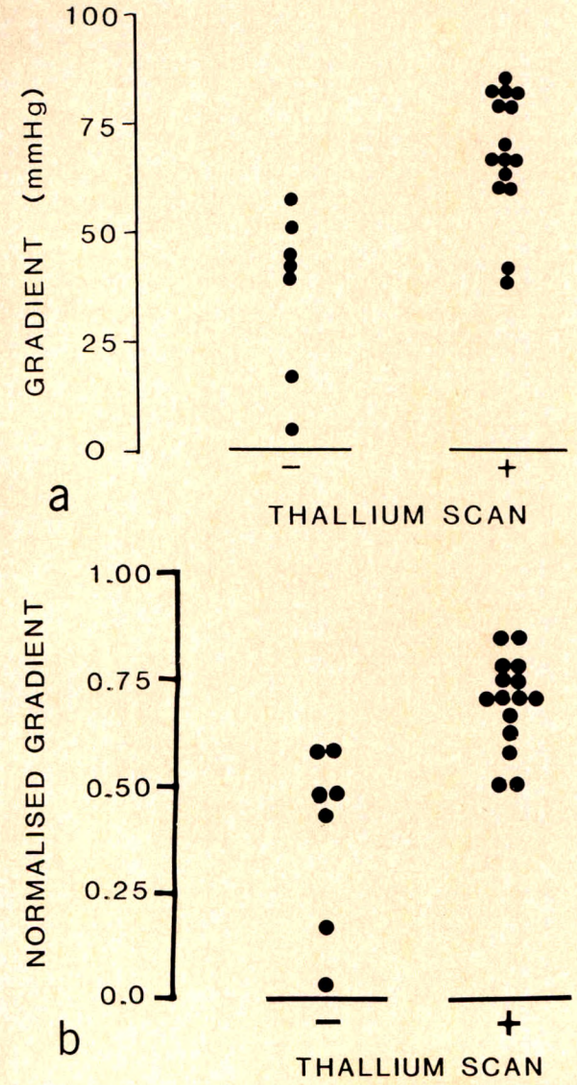

FIGURE 2. The relation between positive (+) or negative (−) thallium-201 scan results and (**a**) absolute gradient and (**b**) normalized transstenotic pressure gradient. The best separation of positive and negative thallium-201 scan results occurs at an absolute gradient of about 50 mm Hg (**a**) and a normalized gradient of about 0.5 (**b**).

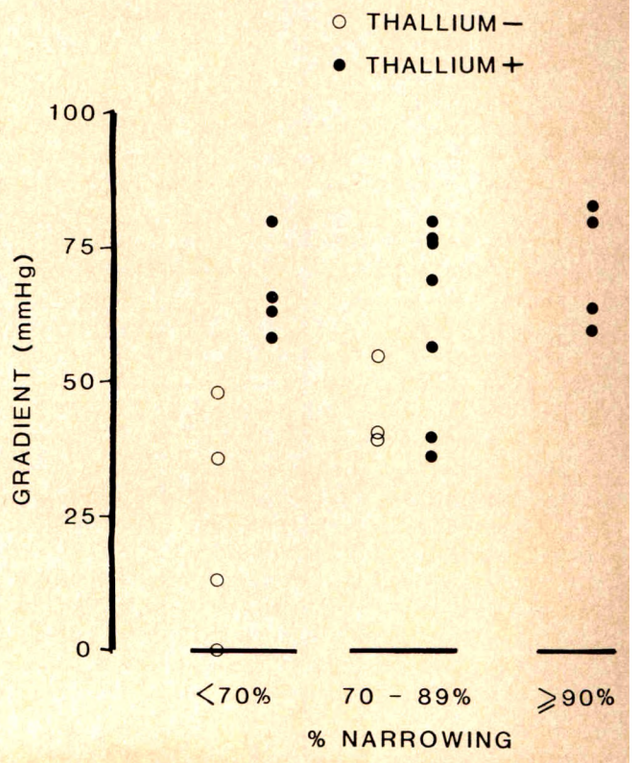

FIGURE 3. The relation between percent luminal diameter narrowing, mean transstenotic pressure gradient and the finding of a positive or negative thallium-201 study. A positive scan result was always associated with a high transstenotic gradient regardless of the percent luminal diameter narrowing.

is similar to that of Bateman et al.[17] However, their absolute pressure gradient threshold for the development of a Tl-201 defect was much lower than ours because their data were collected during open heart surgery, which is accompanied by arterial hypotension. The normalized gradient results between the 2 studies are more comparable, especially when the systematic overestimation of our gradient data that results from the PTCA catheter is considered. Our results showing the independent predictive value of Tl-201 scanning are supported by those of LeGrand et al,[18] who demonstrated that coronary flow reserve correlates better with Tl-201 results than with percent stenosis

Tl-201 scanning has its own deficiencies, with qualitative interpretation requiring experienced observers and a universally acceptable method of quantitative analysis yet to be agreed upon.[3,19] Nevertheless, this study shows that scintigraphy provides unique data relative to the effect of a stenosis on coronary blood flow, a factor that may be important in the evaluation of the individual patient with CAD.

Clinical implications: Evidence is accumulating that a negative Tl-201 stress test is associated with a good long-term prognosis regardless of the coronary anatomy[20] and that scintigraphic detection of myocardial ischemia at stress Tl-201 scintigraphy is a strong predictor of cardiac events in patients with known CAD.[21] The results of our study document a physiologic basis for these observations and lessen the clinical concern that Tl-201 scanning may miss CAD that appears to be significant on angiographic criteria.[22]

Extrapolation of the data obtained in this study to the general clinical applicability of Tl-201 scintigraphy must be done with caution. Our patient population was highly selected, and results different from ours may be expected in patients with previous myocardial infarction, receiving antianginal medication during the stress test, or whose coronary stenoses were multiple or involved vessels other than the LAD.

Our data are most directly applicable to those patients with 1-vessel LAD CAD whose symptoms are atypical and in whom the percent stenosis is not severe. In our study, a positive scan result always indicated a hemodynamically significant stenosis regardless of the angiographic findings. A negative Tl-201 scan was associated with a significantly lower gradient, but one that was still somewhat greater than that found after successful PTCA.[4] Thus, qualitative assessment of Tl-201 scintigrams permits identification of moderate and severe hemodynamic disturbances, but not the milder abnormalities—a potential limitation of this test. However, improvement in detection of these milder abnormalities may be possible with spatial and temporal quantitation of Tl-201 perfusion images,[17,19] tomographic Tl-201 imaging[23] or a more potent form of stress such as a supine bicycle[24] or treadmill[25] exercise test.

Ives®

In angina pectoris*...

Give enough to do the job

ISORDIL®
(ISOSORBIDE DINITRATE)

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode but is widely regarded as useful in the prophylactic treatment of angina pectoris.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.
Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.
Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur. In patients with functional or organic gastrointestinal hypermotility or malabsorption syndrome, it is suggested that Isordil Tembids **capsules** be the preferred therapy since a few patients have reported passing partially dissolved Isordil Tembids **tablets** in their stools; this phenomenon is believed to be on the basis of physiologic variability and to reflect rapid gastrointestinal transit of the tablet.
Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.
Consult direction circular before prescribing.

TWO-WAY LIPID REGULATOR

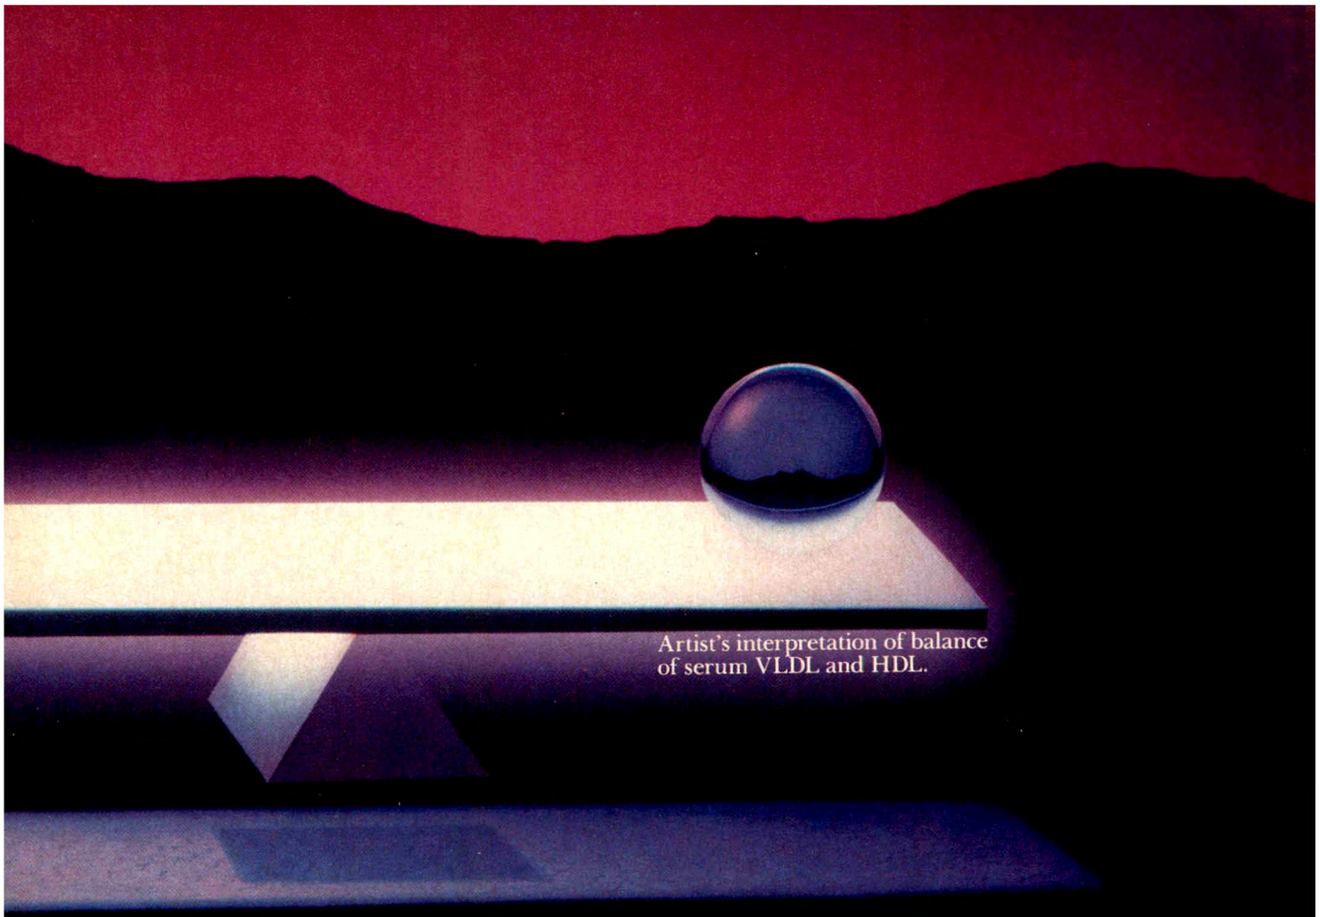
LOPID® *A Balanced Approac*

(gemfibrozil capsules, USP) 300 m

Indicated for adult patients with high serum triglycerides (type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond adequately to diet.

Clinical trials show that Lopid favorably regulates the balance of certain lipoproteins responsible for transport of serum lipids.

- Lowers elevated serum levels of triglyceride-rich very-low-density lipoprotein (VLDL) and, to a lesser extent, cholesterol-ri low-density lipoproteins (LDL)
- Favorably raises serum levels of high-den lipoproteins (HDL)
- Has a side effects profile similar to placebo and no significant abnormalities in clinical/laboratory evaluations
- Plus BID convenience

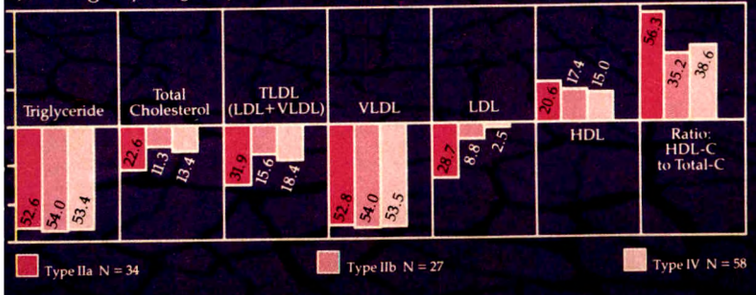


Artist's interpretation of balance of serum VLDL and HDL.

) Therapy of Certain Dyslipidemias

pid-regulating efficacy: en-label phase of US multicenter study end of 12 lunar months*[1]

age percent change from baseline at doses ranging from 1,600 mg/day, majority at 1,200 mg/day (119 patients)†



Diet, exercise and weight loss are the first choice in therapy of lipid disorders.

*Visit every 4 weeks during long-term use of LOPID.

†Data cited on this graph reflect clinical experience based on the multicenter trial. They do not imply an indication for Types IIa and IIb dyslipidemias.

Please see following page for brief summary of prescribing information.

TWO-WAY LIPID REGULATOR

LOPID®

(gemfibrozil capsules, USP) 300 mg

Before prescribing, please see full prescribing information.
A Brief Summary follows.

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO
		Total	VLDL	LDL	HDL	HDL Cholesterol / Total Cholesterol
IIa	−44%	−4.2%	−44.3%	− 5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	− 6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil capsules, USP) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (see WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings.)

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID (gemfibrozil capsules, USP) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels**—LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias**—Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria
Central Nervous System: headache, dizziness, blurred vision
Musculoskeletal: painful extremities
Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia
Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints
Central Nervous System: vertigo, insomnia, paresthesia, tinnitus
Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)
Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL CAPSULES, USP). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

Clinical, Angiographic, Hemodynamic, Perfusional and Functional Changes After One-Vessel Left Anterior Descending Coronary Angioplasty

ROBERT D. OKADA, MD, YEAN L. LIM, MD, CHARLES A. BOUCHER, MD, GERALD M. POHOST, MD, DAVID A. CHESLER, ScD, and PETER C. BLOCK, MD

Percutaneous transluminal coronary angioplasty (PTCA) was successfully performed in 20 patients with 1-vessel left anterior descending (LAD) coronary artery disease. Exercise capacity in terms of peak workload, heart rate and systolic blood pressure all increased significantly 1 week after PTCA. All patients had some decrease in stenosis size and gradient. All patients except 1 had an improvement in functional class. Eight of 12 patients with abnormal exercise electrocardiograms before PTCA had normal electrocardiograms after the procedure. Exercise thallium-201 (Tl-201) myocardial perfusion images obtained in all 20 patients before and 1 week after PTCA were analyzed using a new computer method designed to quantitate regional myocardial Tl-201 distribution, redistribution and clearance rate. Significant improvement in Tl-201 activity was present in the anterior and septal segments of the left ventricle 1 week after PTCA. This increase in Tl-201 uptake was associated with a significant reduction in the amount of Tl-201 redistribution between initial and delayed postexercise images in the same regions. Tl-201 clearance rate in the segments supplied by the dilated vessel also improved significantly. Abnormal Tl-201 lung uptake was seen in 17 patients before and in 4 patients after PTCA. Exercise ejection fraction response and septal wall motion also improved after PTCA of the LAD stenosis in all 17 patients who had exercise radionuclide ventriculography. Improvement in clinical, angiographic and hemodynamic factors as well as in global and regional myocardial perfusion and function occurs after PTCA for 1-vessel LAD coronary artery disease.

(Am J Cardiol 1985;55:347–356)

Percutaneous transluminal coronary angioplasty (PTCA) has become an accepted alternative to coronary artery bypass graft surgery for treating selected patients with coronary artery disease (CAD).[1,2] Data on short- and long-term improvement in myocardial perfusion and function after successful PTCA are steadily emerging.[3–10] This study describes our experience in the short- and long-term follow-up studies of the clinical, angiographic, hemodynamic, perfusional and functional effects of PTCA in patients with 1-vessel left anterior descending (LAD) CAD. A new computer method was used to quantitate regional myocardial perfusion from serial exercise thallium-201 (Tl-201) scintigraphic scans using a technique that allows direct comparison of Tl-201 perfusion in the same anatomic region of the myocardium before and after PTCA.

From the Cardiac Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts. This study was supported in part by Grants HL-21751 and HL-26215 from the U.S. Public Health Service, Bethesda, Maryland. Manuscript received June 1, 1984; revised manuscript received October 24, 1984, accepted October 25, 1984.

Address for reprints: Robert D. Okada, MD, Cardiac Unit, Massachusetts General Hospital, Boston, Massachusetts 02114.

Methods

Patient group: The study population was derived from 37 patients admitted to the Massachusetts General Hospital for PTCA of 1-vessel CAD. The procedure was technically successful in 25 patients. Twenty of these patients had exercise Tl-201 scintigraphy before and after PTCA. These 20 patients constituted the study group, which included 16 men and 4 women, aged 35 to 63 years (mean 51 ± 7) (Fig. 1). Seventeen patients also had radionuclide ventriculography at rest and during exercise. Three patients had previously documented myocardial infarcts. Selective coronary arteriography revealed proximal narrowing in excess of 60% of the luminal diameter, confined to the LAD in 19 patients. One patient had 2 critical narrowings, 1 in the LAD and the other in the diagonal branch of the LAD. All patients had stable but progressive angina (13 were in New York Heart Association class II, 6 were in class III and 1 in class IV) for periods of 3 to 18 months (mean 7 ± 4). All patients were poorly controlled with medical therapy

and were considered suitable for coronary artery bypass graft surgery. None had undergone previous aortocoronary bypass graft surgery. During exercise testing before PTCA, propranolol and long-acting nitrates were not discontinued. Immediately after successful PTCA, β-blocking drugs were discontinued but long-acting nitrates and aspirin were continued for 6 months after PTCA. Exercise Tl-201 scintigraphy and radionuclide ventriculography were performed within 48 hours before and 1 week after PTCA. Nine patients underwent repeat study 6 months after PTCA. Successful PTCA was defined as a reduction in pressure gradient across the narrowing measured during pullback of the dilating catheter or reduction in luminal narrowing at the site of the lesion.

Thallium-201 myocardial scintigraphy: Symptom-limited exercise was performed on a bicycle ergometer in the upright position using a previously described protocol.[11] One minute before the anticipated cessation of exercise, 1.5 to 2.0 mCi of thallium-201 chloride (New England Nuclear) was administered intravenously. An initial postexercise image in the anterior view was collected within 5 minutes after stopping exercise. Intermediate and delayed redistribution images were collected approximately 30 and 180 minutes, respectively, after the initial injection of Tl-201. Ten-minute collections of scintigraphic data were acquired in the anterior, 50° and 70° left anterior oblique (LAO) projections using a conventional Anger scintillation camera (Picker Dynamo Mobile Gamma Camera) interfaced with a mobile nuclear medicine computer system (MUGA-CART, Medical Data Systems). An all-purpose, medium-resolution, parallel-hole collimator and a 25% energy window, encompassing x-ray emissions of 60 to 80 keV, were used. Data was transferred to a VAX 11/780 (Digital Equipment Corp.). The images were then displayed using a DeAnza system teledisplay unit.

The ST-T-wave response to exercise was considered abnormal if there was at least 1 mm horizontal or downsloping ST-segment depression 0.08 second after the J point.

Quantitative interpretation of thallium-201 images: A new computer-assisted method of analyzing Tl-201 images was developed and validated in our laboratory.[12,13] Briefly, an ellipse is placed around the left ventricular (LV) activity in 1 of the 3 serial Tl-201 images. Automatic realignment of the LV activities of the other 2 serial images to fit into the drawn ellipse is performed by horizontal and vertical translation as well as rotation of the images by computer cross-correlation. Background subtraction is performed for each pixel (p) within the original ellipse, taking into account the activity (i) in a "background ellipse," the distance (d) between the pixel point and the background ellipse, and the angle subtended by the 2 adjacent pixels to i from p (Fig. 2). Tl-201 activities in the 3 serial images are normalized to the hottest pixel in the initial postexercise image after a 9-point smoothing. The Tl-201 activity profile curve for the LV myocardium in each image is then determined by the maximal mean peak activity of a running average in 3 pixels within the myocardium on a line perpendicular to the tangent of approximately 200 equally spaced points on the elliptical perimeter. The remainder of the ellipse is subdivided into 5 equal segments along the perimeter and the segments are designated 1 to 5 in a clockwise manner (Fig. 3). To estimate regional myocardial perfusion, mean Tl-201 activity in segments 1 and

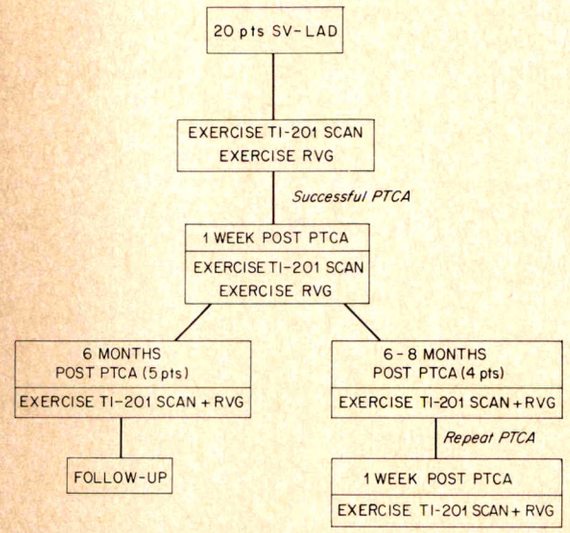

FIGURE 1. Breakdown of patient study group: PTCA = percutaneous transluminal coronary angioplasty; RVG = radionuclide ventriculogram; SV-LAD = single-vessel coronary artery disease involving the left anterior descending (LAD) branch; Tl = thallium.

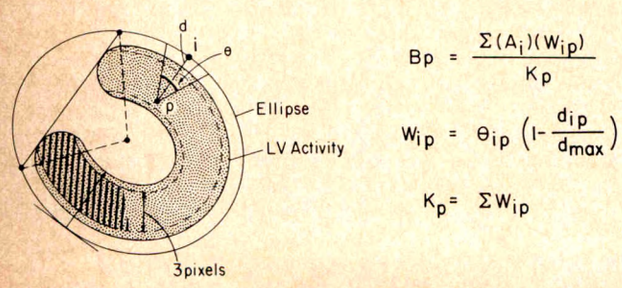

FIGURE 2. Fitting of ellipse (e) around left ventricular (LV) activity (i), background subtraction algorithms, elimination of basal nonmyocardial portion of ellipse and the determination of thallium-201 activity profile from highest mean activity of a 3-pixel (p) wide band within the LV myocardium (see text for details).

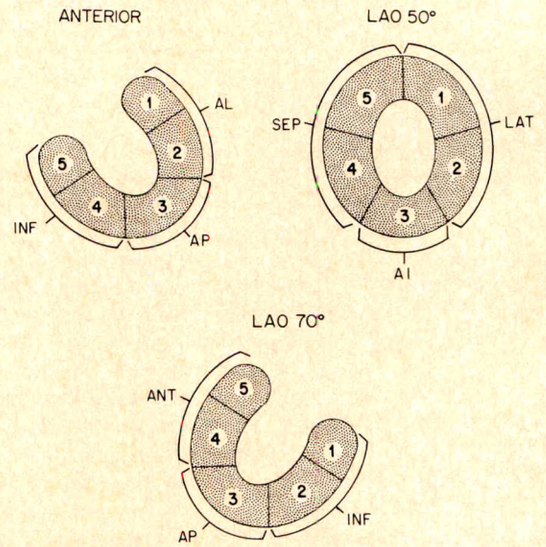

FIGURE 3. Quantitative and qualitative segmentation of left ventricle in relation to coronary artery perfusion territories: AI = apicoinferior; AL = anterolateral; ANT = anterior; AP = apical; INF = inferior; LAO = left anterior oblique; LAT = lateral; SEP = septal; the AL, ANT and SEP segments are in the left anterior descending coronary artery territories; the LAT segment is in the left circumflex coronary artery territory; the INF segments are in the right coronary artery territories.

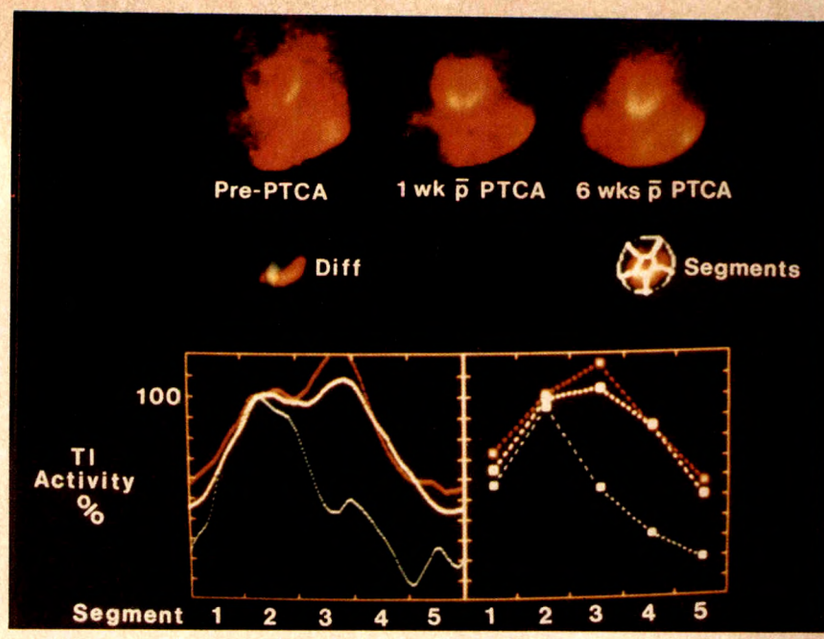

FIGURE 4. Quantitative thallium-201 (TI) activity curves showing segmental TI-201 distribution in the initial postexercise images before, 1 week and 6 months after percutaneous transluminal coronary angioplasty (PTCA) in the left anterior oblique 50° view in 1 patient.

2 in the anterior view (anterolateral segment), segments 4 and 5 in the LAO 45° view (septal segment) and segments 4 and 5 in the 70° LAO view (anterior segment) were ascribed to the LAD territory. Segments 1 and 2 in the 45° LAO view were ascribed to the left circumflex coronary artery distribution. Segments 4 and 5 in the anterior view and segments 1 and 2 in the 70° LAO view were ascribed to the posterior descending coronary artery. The apical segment in each of the 3 views was not ascribed to any 1 specific coronary artery because of overlap of coronary distribution in this region. Mean normalized regional Tl-201 activity of each of the 5 segments in each image was then calculated and plotted in graphic form (Fig. 4). The difference in normalized Tl-201 activity in each segment (delayed minus initial) was taken to represent the amount of regional redistribution of the tracer activity between the delayed and initial images. In addition, the computer-realigned, background-subtracted and normalized Tl-201 image acquired immediately after exercise was directly subtracted from the delayed image after exercise to produce an intensity-coded color functional difference image depicting areas of ischemia-induced Tl-201 redistribution (Fig. 5).

For PTCA scan comparison, the initial postexercise images obtained before and after PTCA were treated as serial images and analyzed using the new computer program. Count activities in the images acquired before, 1 week after and 6 months after PTCA were normalized to the hottest pixel in the initial postexercise image before PTCA (Fig. 4). Improvement in regional Tl-201 uptake was defined as an increase of 10%.

Regional myocardial thallium-201 clearance rate: Using the computer analysis, regional Tl-201 clearance in each LV segment was also quantitated. The clearance rate in each segment, expressed as a mean half-time ($t^{1}/_{2}$ in hours) was calculated by fitting a monoexponential function to the initial, intermediate and delayed image activities.

Qualitative interpretation of thallium-201 images: Images were interpreted qualitatively by 2 experienced observers. The left ventricle was subjectively separated into 3 segments in each projection (Fig. 3). Tl-201 activity in each segment was graded qualitatively on a scale of 0 to 2: 0 = absent activity; 1 = definitely reduced but not absent activity; and 2 = normal. Half grades were used to indicate activity that was either severely but not completely absent (grade 0.5) or activity that was only slightly reduced from normal (grade 1.5). Segments that had abnormally reduced activity (1.0 or less) on the initial view but showed an increase by at least 0.5 grade on the delayed view were considered to have transient defects. Improvement in regional Tl-201 uptake after PTCA was defined as an increase in the mean score of at least 0.5. The intensity of lung Tl-201 activity in the immediate postexercise image was also assessed qualitatively on a scale of 0 to 2: 0 =

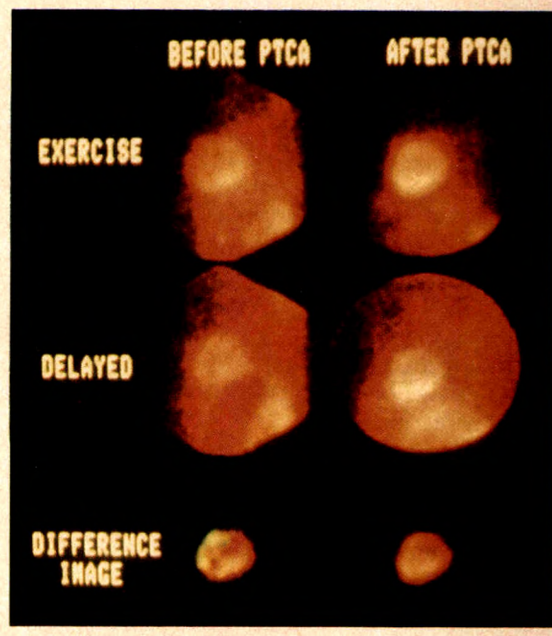

FIGURE 5. Changes in the difference image (delayed-initial) before and 1 week after percutaneous transluminal coronary angioplasty (PTCA). Green color depicts presence of thallium-201 redistribution between the initial and delayed postexercise images.

A1 = 1 week after percutaneous transluminal coronary angioplasty (PTCA); A6 = 6 months after PTCA; B = before PTCA; LAD = left anterior descending artery; NYHA = New York Heart Association; SD = standard deviation; — = not done.

normal activity; 2 = lung and myocardial activity of the same intensity.[14] Lung Tl-201 activity scores of +1 or +2 were considered abnormal.

Exercise radionuclide ventriculography: Rest and exercise gated blood pool scans were acquired in 17 patients after acquisition of delayed Tl-201 images before and after PTCA. The technique used to acquire rest and exercise gated blood pool scans has been previously described.[11]

Analysis of radionuclide ventriculography: Rest and exercise LV ejection fractions were derived from the LAO views using a previously described semiautomated edge detection with a variable region of interest program.[15] Regional LV wall motion was evaluated subjectively as previously described.[12] Three segments in each projection were evaluated: anterolateral, apical and inferior segments in the anterior view; and septal, apicoinferior and posterior segments in the LAO view. Wall motion in each segment was graded on a 0.5 point increment scale from 3 (normal) to −1 (dyskinesia).

Evaluation of the severity of coronary artery stenosis: The severity of a coronary artery stenosis was expressed as a percentage of the pre- and poststenotic luminal diameter. The narrowest portion of the vessel lumen at the site of the stenosis and the normal luminal diameter proximal and distal to the stenosis were measured in at least 3 oblique views in the selected coronary angiograms obtained before and after PTCA. The mean of all individual measurements was calculated. Pressure gradients across the stenosis were measured before and after inflation of the balloon at the stenotic site in all but 2 patients; in the latter 2 the pressure gradients could not be measured because of occlusion of the guiding catheter.

Statistical analysis: Clinical, exercise, radionuclide ventriculographic and Tl-201 data before and 1 week after PTCA in all 20 patients were compared. In 9 patients, data obtained at approximately 6 months after PTCA were also analyzed. For the quantitative analysis of Tl-201 images, regional Tl-201 uptake in the initial postexercise images before and after PTCA were compared. Then, differences in normalized regional Tl-201 uptake between early and delayed images, taken to represent redistribution, before and after PTCA were also compared. Finally, mean clearance of Tl-201 in counts/pixel and clearance rate ($t_{1/2}$) in each LV segment before and 1 week after PTCA were compared.

All data are expressed as mean ± standard deviation. The Student *t* test for paired data was used to evaluate differences between data obtained in the 20 patients both before and 1 week after PTCA. Differences in values between 1 week and 6 months after PTCA were assessed by the analysis of variance with the difference between data before and 1 week after PTCA as covariate. The difference in changes in regional Tl-201 distribution at 1 week after PTCA between patients that required repeat PTCA and those that did not was analyzed using the analysis of variance.

Results

Clinical, angiographic and hemodynamic changes (Table I): In terms of an alleviation of angina, all patients except 1 (no. 6) had improvement in functional class at 1 week after PTCA. The mean functional class improved significantly at 1 week (Fig. 6). In 4 patients (nos. 3, 10, 14 and 17), however, chest pain severe enough to warrant repeat coronary angiography and a second PTCA recurred within 2 to 8 months after the initial procedure. All 20 patients included in the present study had varying degrees of success in the dilatation of their LAD stenosis. The mean percent luminal LAD stenosis decreased significantly after PTCA (Fig. 7). The mean pressure gradient across the stenotic lesion decreased significantly immediately after successful

dilatation (Fig. 7). None of the 20 patients had significant myocardial damage or required emergency coronary bypass graft surgery during and after the angioplasty procedure.

Exercise capacity (Table II): One week after PTCA, the mean exercise time, peak workload, exercise heart rate and systolic blood pressure were significantly higher than values before PTCA (Fig. 8). The mean heart rate at rest and systolic blood pressure were not significantly different. In the 9 patients who had 6-month follow-up studies, except for a higher peak exercise systolic blood pressure, all exercise parameters were not significantly different between the 1-week and 6-month period after PTCA.

Exercise electrocardiography: Before PTCA, 12 of 20 patients had 1 mm or more of ST-segment depression during peak exercise (9 with 1 mm and 1 each with 1.5, 2 and 5 mm of ST depression) (Fig. 6). Only 1 of the 3 patients with electrocardiographic Q waves had further ST-segment depression (1 mm) during exercise.

One week after PTCA, exercise ST depression was abolished in 8 patients, unchanged in 2 and worsened in 2 (and increased from 1 to 2 mm of ST depression in both). The remaining patients had normal exercise electrocardiograms both before and 1 week after PTCA. Eleven patients had typical angina during exercise before PTCA; 7 of these also had positive (1-mm ST depression) exercise electrocardiographic changes. All but 1 patient (no. 17) became asymptomatic 1 week after PTCA. This patient also had worsening of his exercise electrocardiogram (an increment of ST-segment depression by 1 mm) (Table III).

Exercise radionuclide ventriculography: Data on exercise radionuclide ventriculography before and after PTCA were obtained in 17 patients. In these patients, LV ejection fraction at peak exercise increased significantly 1 week after PTCA (Table II, Fig. 9). This increase persisted in all except 1 patient studied at the 6-month follow-up. The mean LV ejection fraction decreased with exercise before PTCA but increased after PTCA. Regional wall motion showed significant im-

provement only in the septal segment during exercise. Abnormal wall motion (score 2.0 or less) in the septal region was present at peak exercise in 11 patients before PTCA. One week after PTCA, septal wall motion during peak exercise was completely normal in 6 of the 11 patients, was improved but remained hypokinetic in 2 and was unimproved in 3 (Table III). Regional wall motion in the remaining left ventricular segments did not change significantly after PTCA.

Exercise thallium-201 scan analysis: Exercise Tl-201 myocardial scintigraphy was obtained in all 20 patients before and 1 week after PTCA. Four of these patients had a second PTCA 2 to 8 months after the first, and in these patients exercise Tl-201 scans were repeated before and 1 week after the second PTCA as well. In addition, exercise Tl-201 scans were also performed in 5 other patients at 6 months after the initial PTCA.

Qualitative analysis of thallium-201 images (Table III): Visual interpretation of Tl-201 scans by 2

observers showed improvement in the initial Tl-201 images after exercise in 14 of the 20 patients 1 week after PTCA. Of these, 8 were assessed as totally normal and 6 had residual abnormalities on their Tl-201 scans. Significant areas of Tl-201 redistribution were abolished in 9 patients and improved in 3 after PTCA. In 5 patients, Tl-201 distribution remained inhomogeneous in the LAD territories and was unimproved by PTCA. Thallium-201 uptake in the lungs in the initial images after exercise was clearly qualitatively abnormal in 10 patients and borderline abnormal in 6 patients before PTCA. After PTCA, the lung uptake of Tl-201 was completely normal in 13 patients and improved but still abnormal in 3 patients.

Quantitative analysis of thallium-201 images (Table IV): When the initial postexercise images obtained before and after PTCA were analyzed as serial images using the new computer program described, the mean normalized regional Tl-201 activity in the myocardial regions supplied by the dilated LAD increased significantly 1 week after PTCA. The mean Tl-201 uptake in the apical segments in all these views also increased significantly. In the anterior and LAO 50° views, the normalized Tl-201 uptake in the nondilated segment did not show significant changes after PTCA. Differences in normalized regional Tl-201 activity between the delayed and early images after exercise, representing redistribution of Tl-201 in ischemic but viable segments supplied by the dilated LAD, showed corresponding significant diminution 1 week after PTCA. The decrease in Tl-201 redistribution after exercise occurred in the septal and apicoinferior segments (segments 3, 4 and 5) in the 50° LAO view and in the anterobasal segment (segment 5) 70° LAO view. Changes in Tl-201 redistribution in the other segments were not statistically significant (Table IV).

After PTCA, 11 patients who had Tl-201 redistribution before PTCA, depicted by the difference images between the delayed and initial images, showed improvement in these segments indicated by disappearance or diminution of the intensity color-coded abnormal regions (Fig. 5, Table III).

No significant correlation was found between either the degree of improvement in initial regional Tl-201 uptake or the amount of Tl-201 redistribution between delayed and initial images, and either the change in percent luminal stenosis or the change in pressure gradient across the LAD lesion before and after successful PTCA.

Regional thallium-201 clearance rate: Patients with 1-vessel CAD present a unique model to study myocardial Tl-201 kinetics. Table V shows the difference in myocardial Tl-201 clearance in the segments supplied by the diseased LAD in the anterior view compared with that in segments supplied by nondiseased coronary arteries. Before PTCA, mean Tl-201 counts increased instead of decreased between the initial and intermediate images in the LV segments supplied by the stenosed LAD. This increase, however, was not statistically significant in this group of 20 patients. In the normal inferior segments, this increase in regional Tl-201 activity between the initial and intermediate images was absent. One week after PTCA, the myocardial clearance of Tl-201 in the segments perfused by

TABLE V Changes in Quantitative Regional Thallium-201 Count-Activity and Clearance Rate in the Initial, Intermediate and Delayed Postexercise Images of the Anterior View After Percutaneous Transluminal Coronary Angioplasty

the dilated LAD resembled that of segments with normal coronary flow. Regional Tl-201 clearance rate (expressed as mean effective $t^1/_2$ [hours]) was abnormally slow in the LAD territories before PTCA and improved significantly after PTCA (Table V).

Comparison of qualitative vs quantitive analysis of thallium-201 scans: Fourteen of the 20 patients had improvement in their Tl-201 scans after PTCA, assessed both qualitatively and quantitatively (Table III). In 1 patient (no. 15), visual interpretation of Tl-201 distribution was assessed as normal before but abnormal after PTCA, whereas quantitation of Tl-201 distribution was normal both before and after PTCA.

Quantitatively generated difference images had the same sensitivity in detecting improvement in regional Tl-201 redistribution (12 of 20) compared with visual and quantitative analysis (Table III). Quantitative analysis of regional Tl-201 distribution in the initial postexercise images, however, showed a greater sensitivity in detecting improved Tl-201 uptake in segments supplied by the dilated LAD (Table VI).

TABLE VI Comparison of Quantitative Versus Qualitative Analysis of Changes in Regional Thallium-201 Distribution After Successful Percutaneous Transluminal Coronary Angioplasty*

LV Segments	Qualitative			Quantitative		
	I	U	W	I	U	W

Inferior (LAO 70°)	0	19	1	2	14	4

* Data refers to number of patients.
I = improved; U = unchanged; W = worsen; other abbreviations as in Table IV.

Six months after percutaneous transluminal coronary angioplasty: In the 9 patients who underwent repeat noninvasive study at 6 months after PTCA, 5 patients (nos. 1, 2, 4, 5 and 7—group A) were asymptomatic at that time. Four patients (nos. 3, 10, 14 and 17—group B) required a second PTCA to the same lesion between 2 to 8 months after the first PTCA because of recurrent angina and restenosis of the original lesion. When changes in regional Tl-201 distribution, redistribution and clearance before and after PTCA were compared in group A and group B patients, greater improvement at 1 week after PTCA was present in group A compared with that in group B patients. These changes did not reach a statistically significant level ($p = 0.07$) in this small number of patients (Table VII).

Discussion

The present study objectively documents the beneficial effects of PTCA on clinical, angiographic and hemodynamic measurements, and on regional myocardial perfusion and function. This study also demonstrates the value of a new computer approach to

TABLE VII Differences in Regional Thallium-201 Distribution in the Left Anterior Descending Coronary Artery Territories at Six-Month Follow-Up in Patients Not Requiring (Group A) and Requiring (Group B) Repeat Percutaneous Transluminal Coronary Angioplasty

LV Segment		Group A (n = 5)	Group B (n = 4)

quantitate changes in regional myocardial perfusion after PTCA from exercise Tl-201 scintigraphic scans. The approach allows objective assessment of the early and long-term effects of PTCA on regional myocardial perfusion. Using the new quantitative technique, the findings at 1 week after PTCA indicated improvement in regional Tl-201 uptake in the ventricular segments supplied by the dilated coronary artery.

Improvement in both regional myocardial perfusion and function after PTCA has been reported by other workers[5–10,16] However, the new approach to quantitate changes in regional Tl-201 distribution presents several unique features not previously described. First, the automatic realignment of serial LV Tl-201 images enables direct comparison of the same anatomic regions of the heart in an objective manner. Second, this method's determination of Tl-201 activity profile curves does not depend on the assumption of a geometric center, which is difficult, if not impossible, to locate accurately in a dynamically contracting heart. Third, this method estimates regional myocardial Tl-201 activity in a transmural fashion from a 3 pixel-wide myocardial band. This is in contrast to other reported methods of quantitating regional Tl-201 distribution from circumferential profiles using peak activity in a single pixel.[17–19] In addition to the assessment of regional Tl-201 distribution, quantitative assessment of regional Tl-201 redistribution between the initial postexercise and delayed images is also an important feature. The presence of Tl-201 redistribution over time indicates ischemic but viable myocardium.[20] The ability to quantitate this redistribution by the present technique is particularly useful in the clinical evaluation of patients before PTCA in order to detect jeopardized by viable myocardium.

The data in the present study suggests a difference in the degree of improvement in postexercise regional Tl-201 distribution in patients whose lesions are likely to restenose compared with those destined to remain patent. In the 5 patients who remained clinically well at 6 months after successful PTCA, the increase in regional Tl-201 distribution was greater than in those who did not do as well clinically. The beneficial effects of PTCA on regional myocardial perfusion persisted at 6 months in patients who remained asymptomatic. However, in 4 patients who required repeat PTCA within 2 to 8 months after the initial PTCA, because of the recurrence of troublesome symptoms and coronary restenosis at the same site, the improvement in Tl-201 distribution 1 week after the initial PTCA was not as great as that for patients who remained clinically well at the 6-month follow-up. Although the differences in the degree of improvement in regional Tl-201 activity in these 2 groups did not reach a statistically significant level, with more patients followed up over a longer period, this difference in regional Tl-201 uptake after PTCA may be found to be an indicator of patients who might require closer clinical supervision or earlier repeat angiography, or both.

This group of 20 patients with isolated LAD CAD presents a unique model for studying the myocardial clearance of Tl-201 under normal and ischemic conditions. It has been well documented that the Tl-201 clearance rate from ischemic myocardium is slower than that from normally perfused myocardium.[21–24] In the present study group, the myocardial Tl-201 did not washout significantly between the initial and 30-minute imaging times in the diseased segments before PTCA. After PTCA, the regional Tl-201 counts decreased between the initial and 30-minute imaging times in both the LAD supplied and the normally perfused segments. The post-intermediate image clearance rate was also restored to normal in the previously jeopardized segments after PTCA. Thus, the Tl-201 clearance rate appears to be an additional sensitive index for assessing reversal of ischemia after PTCA.

Of the 17 patients who had exercise radionuclide ventriculography before and after PTCA, 8 patients who had an exercise-induced decrease in ejection fraction before PTCA either had a significant increase or a flat ejection fraction response to exercise after PTCA. Regional wall motion, most notably in the septum, was also improved in several patients after PTCA. These findings of improved global and regional LV function after PTCA closely resemble those results reported after successful coronary artery bypass graft surgery.[25–27]

In conclusion, we have objectively demonstrated the immediate and long-term beneficial effects of PTCA on regional myocardial perfusion, overall clinical status and myocardial function in patients with 1-vessel LAD CAD. The noninvasive technique used in the present study may have wider clinical applications, such as the assessment of changes in regional coronary perfusion and myocardial viability after mechanical or pharmacologic intervention in the setting of acute myocardial infarction.

Early Detection of Restenosis After Successful Percutaneous Transluminal Coronary Angioplasty by Exercise-Redistribution Thallium Scintigraphy

WILLIAM WIJNS, MD, PATRICK W. SERRUYS, MD, JOHAN H.C. REIBER, PhD, PIM J. de FEYTER, MD, MARCEL van den BRAND, MD, MAARTEN L. SIMOONS, MD, and PAUL G. HUGENHOLTZ, MD, *With the statistical assistance of* JAN G.P. TIJSSEN

The value of exercise testing and thallium scintigraphy in predicting recurrence of angina pectoris and restenosis after a primary successful transluminal coronary angioplasty (PTCA) was prospectively evaluated. In 89 patients, a symptom-limited exercise electrocardiogram (ECG) and thallium scintigraphy were performed 4 weeks after they had undergone successful PTCA. Thereafter, the patients were followed for 6.4 ± 2.5 months (mean ± standard deviation) or until recurrence of angina. They all underwent a repeat coronary angiography at 6 months or earlier if symptoms recurred. PTCA was considered successful if the patients had no symptoms and if the stenosis was reduced to less than 50% of the luminal diameter. Restenosis was defined as an increase of the stenosis to more than 50% luminal diameter. The ability of the thallium scintigram (presence of a reversible defect) to predict recurrence of angina was 66%, vs 38% for the exercise ECG (ST-segment depression or angina at peak workload). Restenosis was predicted in 74% of patients by thallium scintigraphy, but only in 50% of patients by the exercise ECG. Thus, thallium scintigraphy was highly predictive but the exercise ECG was not ($p < 0.005$). These results suggest that restenosis had occurred to some extent already at 4 weeks after the PTCA in most patients in whom it was going to occur.

(Am J Cardiol 1985;55:357–361)

Restenosis after primary successful percutaneous transluminal coronary angioplasty (PTCA) occurs in 19 to 36% of patients within the first 6 months after the procedure.[1–5] This restenosis may manifest itself by changes in the patient's clinical status and may be detected by noninvasive diagnostic tests or by coronary angiography. Scholl[2] and Hirzel[6] and their co-workers showed that an abnormal response on the exercise electrocardiogram (ECG) and a myocardial perfusion defect on the thallium scintigram is associated with angiographically documented restenosis of the dilated vessel or is a sign of the presence of additional disease. The present study was performed to determine the value of early noninvasive testing in the prediction of restenosis and recurrence of symptoms. The study patients had undergone technically successful PTCA, which resulted in a "complete" anatomic correction. They were all free of angina pectoris up to the time of exercise electrocardiography and thallium scintigraphy, which were performed a median of 4 weeks after PTCA. Follow-up data regarding subsequent recurrence of symptoms and repeat coronary angiography a median of 6 months after the procedure were compared in a prospective manner with the noninvasive test results obtained at 4 weeks.

Methods

Between September 1980 and September 1983, 296 consecutive first PTCA procedures for stable or unstable angina pectoris were attempted at the Thoraxcenter; 221 were primary successes. The 162 patients from our own institution were asked to cooperate with a follow-up protocol, which included an exercise electrocardiogram and thallium scintigram 4 to 6 weeks after the procedure, a visit to the outpatient clinic at 2-month intervals and a repeat angiogram at 6 to 8 months. The 59 patients referred from institutions in other cities were excluded. One hundred twenty patients met the inclusion criteria for the present study: "complete" anatomic correction,

TABLE I Characteristics of the Angioplasty Procedure

i.e., no significant residual coronary obstructions after PTCA; absence of angina until the time of exercise testing; and ability to complete the exercise test. Thirty-one patients refused to undergo repeat coronary angiography. This report is thus based on the prospective evaluations of 89 patients, 74 men and 15 women. A single stenosis was dilated in 85 patients and 2 stenoses were dilated in 4 patients. The dilated vessel was the left anterior descending artery in 59 patients, the left circumflex in 9, the right coronary artery in 24 and the distal anastomotic site of a saphenous vein bypass graft on the left anterior descending coronary artery in 1 patient. PTCA was performed according to the technique of Gruentzig,[1] with Schneider equipment through a femoral route. Details regarding the procedure used in our laboratory were described previously.[7,8] The PTCA procedure was considered successful when the residual stenosis was less than 50% in diameter with a good run off and filling of the distal vessel at angiography. In the 91 stenoses with satisfactory recordings, the residual pressure gradient (normalized for the mean aortic pressure) was less than 0.20 in 63 cases and less than 0.40 in 25 cases.

In an attempt to reduce the restenosis rate,[3,5] all patients received nifedipine, 10 mg every 2 hours for the first 8 hours after the procedure and received maintenance therapy on salicylic acid, 500 mg/day, and nifedipine, 10 mg 3 to 6 times daily, until repeat angiography was performed. Beta-blocking agents were stopped unless the patient had hypertension. Repeat angiography was performed 7.0 ± 2.3 months (mean ± standard deviation) after PTCA in the patients who remained asymptomatic and 4.9 ± 2.3 months after PTCA in patients who had recurrent angina during follow-up. Coronary angiography was performed in multiple views (including hemiaxial views for the left coronary artery) and were interpreted visually without knowledge of the initial noninvasive test results. The clinical definition of restenosis was an increase of the diameter stenosis of the dilated lesion above the 50% level. In addition, quantitative analysis of the dilated stenosis was obtained in the same angiographic projection for each angiogram by means of our computer-based coronary angiographic analysis system.[9] Based on these accurate and more objective measurements of stenosis severity,[10] the definition of restenosis used by the National Heart, Lung, and Blood Institute (NHLBI) registry[4] was applied as well, i.e., an increase in stenosis of at least 30% from the immediate post-PTCA result or the loss of at least half the initial gain in diameter.

The exercise studies were performed 4.7 ± 1.9 weeks after PTCA. The subjects performed a symptom-limited exercise test on the bicycle ergometer with stepwise increments of 20 W/min. The 3 orthogonal leads XYZ of the Frank lead system were recorded and analyzed as previously described.[11] The reported sensitivity and specificity for the diagnosis of significant coronary disease were 85% and 90%, respectively. Horizontal ST depression of 0.1 mV or greater and typical angina during exercise were considered as abnormal (or positive) responses. One minute before peak exercise, thallium, 1.5 mCi, was injected intravenously. Imaging was started 5 minutes later in 3 views: anterior, left anterior oblique 45° and 65°. Static planar images (500 kcounts full field, zoom 2 ×) were obtained after exercise and 4 hours later with a Searle Phogamma V camera. The scintigraphic images were processed on a DEC gamma-11 system with a quantification procedure developed at our institution.[12] The late image was corrected for acquisition time differences with respect to the early image. The exercise and redistribution images were registered on the basis of the detected positions of point sources taped to the patient's chest. After automated left ventricular contour detection[13] and interpolative background correction,[14] circumferential profiles were computed at 6° intervals. The profiles of the early and late images were normalized for the maximal value in the early image (100%) excluding the outflow tract of the left ventricle. The analog Polaroid® images from the gamma camera, the processed images and the circumferential profiles were analyzed prospectively on a routine basis by 3 experienced observers without knowledge of the angiographic data. The thallium uptake in a total of 11 segments was scored both in the postexercise and late images on a 5-point scale: 0 = no thallium uptake; 1 = severely abnormal; 2 = definitely abnormal; 3 = doubtfully abnormal; and 4 = normal. The following segments were defined: posteroseptal, inferior, apical and anterolateral in the anterior view; anteroseptal, apical and posterolateral in the left anterior oblique 45° view; and anterior, apical, inferior and posterior in the left anterior oblique 65° view. The scores of all segments were summed per patient and the difference between late and early postexercise sums was taken as a measure of the amount of redistribution. An increase in thallium uptake score of 2 points or more between postexercise and late images was taken as the cutoff between normal (absence of exercise-induced ischemia) and abnormal (presence of exercise induced ischemia) scintigrams. Persistent defects without redistribution were considered to represent scars

TABLE III Positive and Negative Predictive Values of the Noninvasive Tests

	Restenosis					
	50% Diameter		NHLBI Criteria*		Recurrent Angina

AP = angina pectoris; ECG = electrocardiogram; NHLBI = National Heart, Lung, and Blood Institute.

without exercise-induced ischemia. With this analysis, the previously reported sensitivity and specificity for the diagnosis of significant coronary artery obstructions were 80 and 88%, respectively.[12] The patients were followed up in the outpatient clinic until occurrence of typical angina pectoris or a new myocardial infarction. The follow-up duration was 6.4 ± 2.5 months. No patient died during this period.

Results are presented as mean ± standard deviation. The *t* test for paired or unpaired data was used whenever appropriate. The positive predictive value for restenosis (or recurrent angina) was calculated as the frequency of restenosis (or recurrent angina) in those with abnormal test results. The negative predictive value for the absence of restenosis (or recurrent angina) was calculated as the frequency of long-term success in those with normal test results. Differences between correct and incorrect classifications by exercise ECG vs thallium were evaluated by the McNemar test.

Results

The characteristics of the PTCA procedure are listed in Table I for 2 groups: patients with restenosis of the dilated vessel, i.e., diameter stenosis at repeat angiography more than 50% (n = 35), and patients with long-term success (n = 54). There was no significant difference between these 2 groups in the pressure gradient across the stenosis either before or after PTCA. The exercise test results and the recurrence of symptoms during the follow-up are summarized for both groups in Table II. The mean timing of exercise testing after PTCA and the resultant maximal workloads and heart rates achieved were similar for both groups. Ninety-two percent of the patients reached 80% of their predicted maximal workload. An abnormal exercise ECG was observed in 26 patients: 21 had ST-segment depression, 4 had angina at peak workload and 1 patient had both.

Exercise-induced ischemia as assessed by the thallium redistribution was observed in 35 patients. During the follow-up, angina recurred in 29 patients. No patient had a new myocardial infarction in the territory of the dilated vessel. The positive and negative predictive values of each single test are shown in Table III. Thallium was superior to the exercise ECG both for the prediction of recurrent stenosis and recurrent angina (both $p < 0.005$). The predictive value for recurrent stenosis of the 4 combinations of test results is shown in Figure 1. An abnormal scintigraphic response was associated with a high incidence of restenosis, which was not influenced by the result of the exercise ECG: 71% of restenoses when both tests were abnormal vs 76% when tests were discordant. Conversely, a normal scintigraphic response was associated with a low incidence of restenosis, which was also not influenced by the result of the exercise ECG: 14% of restenosis when both tests were normal and 25% when tests were discordant.

The value of combined noninvasive test results for the prediction of recurrent angina is shown in Figure 2. Angina recurred in 64% of patients with both tests abnormal and in 67% of patients with only thallium abnormal. In the presence of a normal scintigraphic response, the recurrent angina was about 10%, regardless of the result of the response on the exercise ECG.

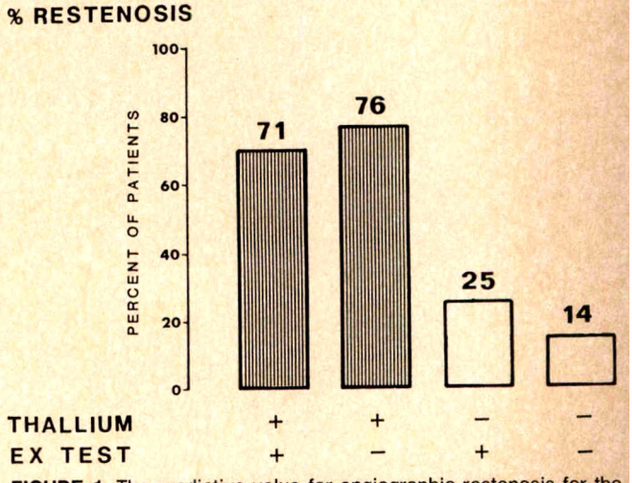

FIGURE 1. The predictive value for angiographic restenosis for the possible combinations of noninvasive test results: (+) = abnormal test and (−) = normal test; EX TEST = exercise electrocardiogram. **Shaded columns** represent the patients with abnormal scintigraphic responses. Both test results were abnormal in 14 and normal in 42 patients; only thallium was abnormal in 21 and only exercise ECG in 12 patients.

By the NHLBI definition of restenosis based on the quantitative analysis of the angiograms, only 6 patients were categorized in another group; 37 had restenosis by these criteria. The predictive value of the noninvasive tests was not significantly different: 54% restenosis when the exercise ECG was abnormal vs 74% restenosis when the scintigram was abnormal (Table III).

Discussion

The present report demonstrates that early assessment of myocardial perfusion by exercise thallium scintigraphy has a high predictive value for restenosis and recurrence of angina in patients who underwent a technically satisfactory PTCA. Previous studies[2,6,15–17] assessing the results of PTCA by noninvasive tests have focused on the reversibility of the ischemic changes after a successful procedure and on their induction at the time of recurrence. However, more recently, DePuey et al[18] reported that failure to increase ejection fraction or the development of a new regional wall motion abnormality during exercise radionuclide ventriculography early after PTCA predicted restenosis at 4 to 12 months in 73% of 41 patients. Their findings and those of the present study suggest that restenosis had occurred to some extent already at 4 weeks in most patients in whom it was documented later. This observation raises speculations about the underlying mechanism of restenosis after dilatation. Fibrocellular proliferations as a reparative response to coronary wall laceration has been described in necropsy studies[19] and may represent the pathologic substrate of early restenosis. In analogy with aortic dissection, exposure of vascular smooth muscle cells to blood may trigger an exuberant tissue reaction, leading to obliteration of the false channel and eventually of the functional lumen. Preliminary data[20] from experimental angioplasty in pigs suggest that balloon dilatation is a potent stimulus to early platelet deposition and subsequent intimal hyperplasia. In this model, the reparative process was observed as early as 2 weeks after the procedure. If present in patients, such ongoing processes may have induced the observed perfusion abnormalities. Since only successful cases were included and the decrease in stenosis severity and in the transstenotic pressure gradient were comparable in patients with restenosis and long-term success, there is no evidence that recurrence occurred predominantly in patients in whom the dilatation was incomplete. In this study, the high predictive value of the perfusion scintigram contrasts with the poor predictive value of the exercise electrocardiographic response, especially for the prediction of restenosis.

This could be explained by a lower sensitivity of the exercise ECG compared with thallium scintigraphy in the detection of moderate coronary artery narrowing. The combination of a normal exercise ECG with a reversible thallium perfusion abnormality could be an early indicator of the presence of a noncritical stenosis, still insufficient to induce ST-segment depression during exercise.[21] Indeed, 66% of the patients with an initially abnormal scintigram became symptomatic at a later stage during the follow-up period.

The problem of defining restenosis is not trivial. Applying the stringent criteria of the NHLBI registry to visual estimations of stenosis severity has major limitations, due to the large intra- and interobserver differences in interpretation, especially for stenoses between 20 and 80%.[22] Therefore, the stenoses were analyzed by computerized edge detection. Although this method may not be optimal after angioplasty,[9] it provides an objective and quantitative measurement, avoiding unintentional bias in reading the angiograms. This complex definition of restenosis resulted however in similar findings as the usual clinical approach based in the presence or the absence of a hemodynamically significant stenosis (>50% luminal diameter). By this clinical definition, restenosis of the dilated artery was observed in 39% and recurrent angina pectoris in 33% of the patients.

The true incidence of recurrence is probably lower because most of the patients who refused to undergo repeat angiography were asymptomatic. The patient population is thus biased in favor of those with recurrent stenosis. The clinical implication of these findings for the routine management of patients who undergo PTCA remains to be established. Certainly we share with DePuey et al[18] the conclusion that an abnormal noninvasive test early after PTCA in an asymptomatic patient is an indication for close clinical monitoring in view of the high chance of recurrence of symptoms. We believe that decisions to perform repeat angiography, followed by a redilatation when restenosis is found, should primarily be based on the severity of angina rather than on the results of the testing procedure. This is analogous to the issue of bypass surgery for documented coronary artery disease in asymptomatic patients, particularly since no benefit of surgical intervention over pharmacologic treatment was shown in mildly or nonsymptomatic patients.[23] Until the outcome

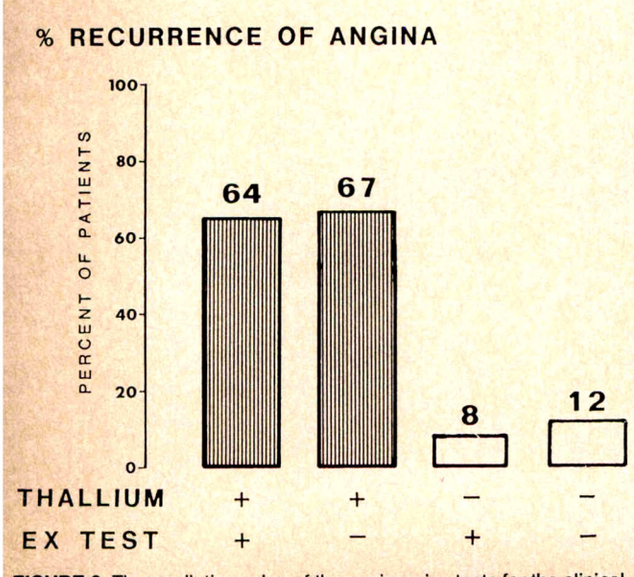

FIGURE 2. The predictive value of the noninvasive tests for the clinical endpoint (recurrent angina); other abbreviations as in Figure 1.

of prophylactic PTCA is studied, the procedural complications and incomplete success rates militate against performing PTCA when diagnostic testing reveals restenosis in the absence of symptoms.

Acknowledgment: We acknowledge G. Koster for expert preparation of the manuscript. We are especially grateful to P. van Eldik and J.W. Deckers, MD, for analyzing the coronary angiograms.

Comparison of Preoperative, Operative and Postoperative Variables in Asymptomatic or Minimally Symptomatic Patients to Severely Symptomatic Patients Three Years After Coronary Artery Bypass Grafting: Analysis of 423 Patients

PIM J. de FEYTER, MD, PATRICK W. SERRUYS, MD, RONALD W. BROWER, PhD, MARCEL van den BRAND, MD, HARALD J. ten KATEN, BSc, PAUL G. HUGENHOLTZ, MD, and EGBERT BOS MD

During a follow-up period of 3 years, among a consecutive series of 423 patients who gave informed consent for recatheterization both 1 and 3 years after coronary artery bypass grafting, the incidence of severely symptomatic patients with New York Heart Association class III or IV was 19% (79 of 423). The predictive value of approximately 80 clinical, angiographic and perioperative variables was too low to be of clinical value. Adverse clinical outcome was associated with a high closure rate of the grafts. Forty-six percent of the patients could not undergo reoperation because of unsuitable coronary anatomy. With intensive medical therapy half of these patients improved to functional class I or II, while of those patients who were reoperable 32% improved to class I or II with intensive pharmacologic treatment instead of reoperation. The nonresponders underwent reoperation, which resulted in improvement of symptoms to functional class I or II in most (83%). (Am J Cardiol 1985;55:362–366)

In this report we focus on patients who became severely symptomatic after coronary artery bypass grafting (CABG) during 3 years of follow-up. The following questions were posed: What is their incidence? Can an adverse postoperative outcome be predicted from preoperative or perioperative variables? What are the explanatory factors for this adverse outcome? What is the reoperability rate, how were these patients actually managed and what was their clinical outcome?

Methods

From January 1976 to December 1979, a consecutive series of 637 patients underwent CABG at the Thoraxcenter, Rotterdam. All patients had symptoms before operation despite adequate medical treatment. The complaints were stable or unstable angina. Patients with coexisting valvular or congenital heart disease, those who had undergone left ventricular (LV) aneurysmectomy, surgery for dysrhythmias, and those with a life expectancy of less than 5 years because of other serious disease were excluded. Four hundred twenty-three patients (66%) agreed to undergo recatheterization at 1 and 3 years after operation, irrespective of their postoperative complaints. These patients constitute the study population. Before CABG, 34% of the patients did not agree to undergo 2 postoperative catheterizations. On the basis of clinical data (age, sex, severity of symptoms and previous myocardial infarction [MI]) and preoperative angiographic data (severity and extent of coronary artery disease (CAD) and LV function), both groups (no informed consent vs informed consent) were comparable.

Of the 423 patients who formed the study population, 3 died during operation. During a follow-up of 3 years, 79 patients have become severely symptomatic and 341 patients have had no or mild symptoms. (Fig. 1).

Follow-up and management: All patients were seen every 6 months in the outpatient department over the 3-year period. Severe symptoms (persistent or recurrent) were defined as angina pectoris of New York Heart Association (NYHA) functional class III or IV severity. All but 1 of the 79 severely symptomatic patients could be evaluated with angiography. Reoperability was assessed in joint discussion between the

cardiac surgeons and cardiologists. After assessment of reoperability, all severely symptomatic patients were initially treated with intense pharmacologic therapy. The patients who had no adequate response to this treatment and those who desired a reoperation (a minority) underwent reoperation. Intensive pharmacologic therapy consisted of nitrates (short- and long-acting) and β-adrenergic agents, inasmuch as calcium antagonists were not available before 1979.

Of the 341 patients with no or mild symptoms despite initial agreement for recatheterization, 276 actually underwent this procedure at 1 year and 158 at 3 years. The patients who did not undergo recatheterization refused upon reconsideration. Clinically available information indicated that the patients who refused recatheterization did not differ from those who consented.

Coronary angiography: Selective coronary angiography was performed in multiple projections including hemiaxial views. The degree of luminal narrowing was coded according to the guidelines of the American Heart Association.[1] The degree of luminal narrowing was assessed visually and scored as less than 50%, 50 to 89%, 90 to 99%, and 100%. The bypass grafts were infused selectively with contrast medium to establish patency.

The severity of the underlying CAD before and after CABG was quantified by the coronary score system developed by Leaman and Brower and their co-workers.[2,3] This coronary score represents the combined effect of the disease in a segment of the coronary artery weighted according to the significance of that vessel. A score of 0 would indicate no obstructive disease, whereas the higher the score, the greater the severity of disease.

In deriving the postoperative coronary score, a vessel segment supplied by a graft was considered to take over the disease factor, if any, of the graft, provided there was no other total occlusion distal to this segment and proximal to the graft anastomose. This postoperative score represents remaining CAD, taking into account disease in the native system as well as closure of grafts.

From this principle, 2 additional postoperative scores could be derived: the coronary score corrected for CABG immediately after surgery and during follow-up, assuming all grafts patent and normal, representing remaining disease in the native coronary system that could not be effectively bypassed, and the coronary score corrected for CABG assuming all grafts closed (or not placed), representing severity of disease in the total native coronary system during follow-up.

Statistical analysis: Univariate statistical analysis was performed using either the chi-square test or Student t test when appropriate using double-sided distributions. Multivariate discriminant function stepdown function analysis was performed with program P7M of the BMDP statistical package.

Results

Characteristics of the population: Of the 423 patients, 93% were men; mean age was 51.6 ± 7.1 years. Sixty-eight percent had a previous MI. Sixteen percent of the patients had 1-vessel, 27% had 2-vessel, 50% had 3-vessel and 6% left main CAD. Sixty percent of the patients had an ejection fraction greater than 0.50, 24% between 0.30 and 0.50, and 2% less than 0.30; the ejection fraction was unknown in 13%. The perioperative mortality was 0.7% (3 of 423 patients). During a follow-up of 3 years the incidence of severely symptomatic patients was 19% (79 of 420 patients) (Fig. 1).

Predictability of postoperative clinical outcome: The most important pre- and perioperative clinical and angiographic variables are presented in Tables I, II and III. Multivariate analysis showed that 3 variables had independent predictive value for postoperative severe angina: a low preoperative coronary score, performance of endarterectomy, and absence of previous MI. Together, these 3 variables correctly predicted 60% of the patients with adverse clinical outcome and 62% of the patients with no or mild symptoms.

Explanatory factors for severe symptoms after bypass surgery: The results of pre-, peri- and postoperative angiographic variables are shown in Table IV and Figure 2. An adverse clinical outcome is associated with a higher corrected coronary score, caused by a lower patency rate. There were no differences in preoperative extent of CAD, the number of nonbypassed stenoses, or progression of disease in the native coronary circulation.

Reoperability, management and clinical outcome: Reoperability was assessed in 70 patients; 46% of them were unable to undergo reoperation for technical reasons. The actual management and resulting clinical outcome are shown in Figure 3. Intensive pharmacologic treatment was offered to all patients who could not undergo reoperation.

Discussion

Many patients suffer from angina pectoris after CABG. During a follow-up study of 75 unselected patients, Campeau et al[4] found a recurrence rate of angina pectoris of 38% at 1 year after operation, 45% at 3 years and 63% at 7 years. In a follow-up study of 748 patients for 5 to 94 months, Cameron et al[5] found a recurrence rate of angina of 21% at 1 year to 37% at 6 years. The severity of angina was generally milder than before operation. The European Coronary Surgery Study[6] reported a postoperative recurrence rate of angina of 42% at 1 year and 51% at 3 years. In approximately half of the patients the symptoms were unchanged or even

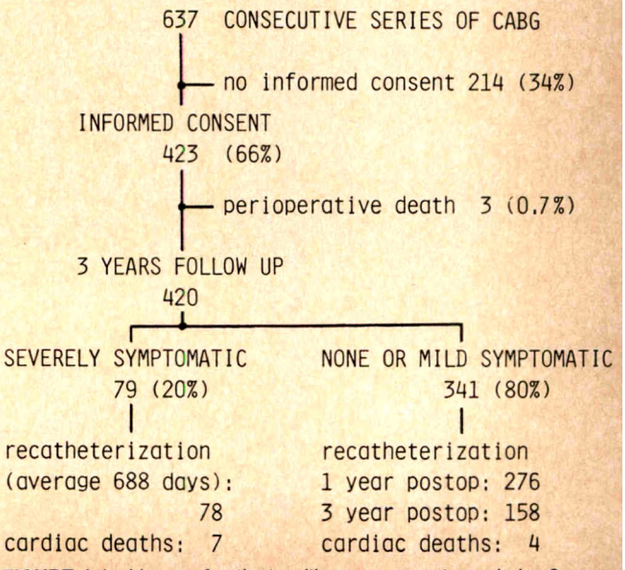

FIGURE 1. Incidence of patients with severe symptoms during 3 years follow-up after coronary artery bypass surgery (CABG).

TABLE I Predictive Value of Clinical Variables

Variable	Severely Symptomatic Patients (n = 79) n (%)	No or Mild Symptoms (n = 340) n (%)	p Value
Men	73 (92)	316 (93)	NS
Age >53 yr	35 (44)	171 (50)	NS
History of MI	46 (58)	240 (71)	NS
Cigarette smoker	77 (97)	295 (87)	NS
Cerebrovascular disease	21 (27)	80 (24)	NS
Diastolic BP >100 mm Hg	33 (42)	101 (30)	NS
Diabetes mellitus	6 (8)	17 (5)	NS
Family history of CAD	41 (52)	178 (52)	NS
4th heart sound	17 (22)	43 (13)	NS
CT ratio >0.5	40 (51)	167 (49)	NS
Total serum cholesterol >7.0 mmol/liter	35 (44)	146 (43)	NS
Serum triglycerides >2.5 mmol/liter	22 (28)	91 (27)	NS

p value: univariate analysis, χ^2 test.
BP = blood pressure; CAD = coronary artery disease; CT = cardiothoracic; MI = myocardial infarction; NS = not significant.

TABLE II Predictive Value of Preoperative Angiographic Variables

Variable	Severely Symptomatic Patients (n = 79) n (%)	No or Mild Symptoms (n = 340) n (%)	p Value
Pain during APST	36 (46)	158 (46)	NS
LVEDP >13 mm Hg	35 (44)	183 (54)	NS
EF >0.60	38 (48)	139 (41)	NS
3-vessel CAD	43 (54)	208 (61)	NS
Multivessel CAD	66 (84)	291 (86)	NS
Preoperative coronary score >15	23 (29)	138 (41)	<0.05

p value: univariate statistics, χ^2 test.
APST = atrial pacing stress test; CAD = coronary artery disease; EF = ejection fraction; LVEDP = left ventricular end-diastolic pressure; NS = not significant.

TABLE III Predictive Value of Perioperative Variables

Variable	Severely Symptomatic Patients (n = 79) n (%)	No or Mild Symptoms (n = 340) n (%)	p Value
Multiple grafts placed	69 (87)	280 (82)	NS
Lowest flow per graft <45 ml	49 (62)	211 (62)	NS
Total graft flow >50 ml	64 (81)	292 (86)	NS
Coronary endarterectomy	39 (49)	126 (37)	0.05
Duration ECC >110 min.	36 (46)	155 (46)	NS
Duration ACC >35 min.	37 (47)	138 (41)	NS
Perioperative infarction	4 (5)	18 (5)	NS
IABP assistance	3 (4)	24 (7)	NS

p value: univariate analysis, χ^2 test. ACC = aortic cross-clamping time; ECC = extracorporeal circulation; IABP = intraaortic balloon pumping; NS = not significant.

worse than before operation. Rahimtoola[7] reported that CABG reduced symptoms in 76 to 90% of patients; 33 to 55% became asymptomatic, 5 to 6% showed deterioration of symptoms after surgery, and angina recurred at an annual rate of 2 to 4%.

Laird-Meeter et al[8] studied 1,041 patients with a follow-up of 1 to 10 years (mean 3.5). The incidence of postoperative angina pectoris at 1 year was 30%, at 3 years 46% and at 8 years 50%. However, 89% of these symptomatic patients felt themselves improved by surgery. In this study, approximately 40% of the operated patients reported angina pectoris during a follow-up period of 3 years, which is in agreement with the studies cited earlier. Half of these patients had severe angina pectoris. Thus the incidence of severe symptomatic patients with NYHA class III to IV during a 3-year follow-up was 19%; most of the patients had class III symptoms.

Predictability of clinical outcome after bypass surgery: Obviously, patient management could be

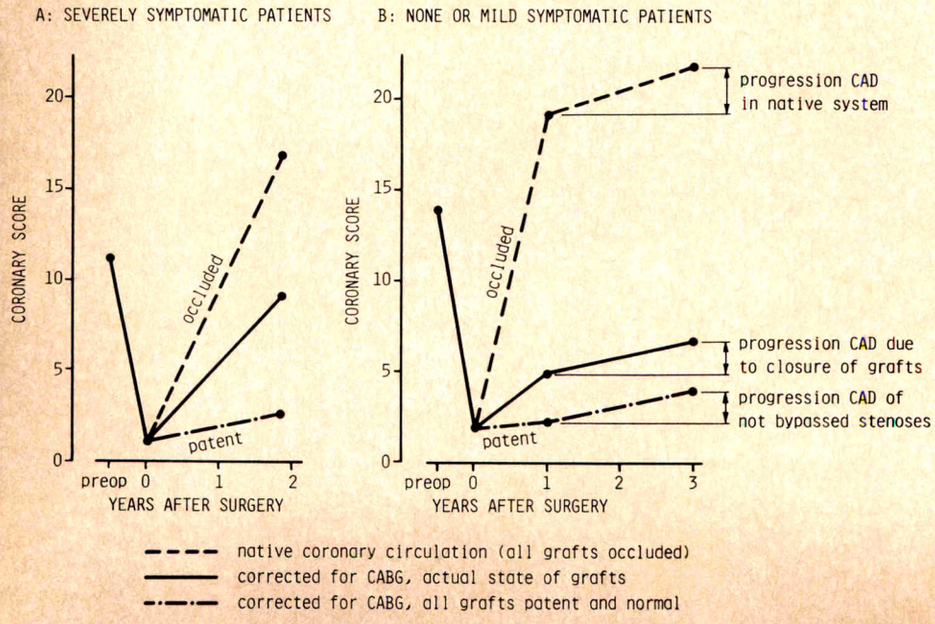

FIGURE 2. Progression of coronary artery disease (CAD) in severely symptomatic patients (**A**) and asymptomatic or mildly symptomatic patients (**B**). CABG = coronary artery bypass graft surgery.

TABLE IV Explanatory Factors for Severe Symptoms After Coronary Artery Bypass Grafting

Variable	Severely Symptomatic (n = 79)	No or Mild Symptoms (n = 340)	
	Preoperative		
LV end-diastolic pressure	17 ± 8	17 ± 6 (NS)	
Ejection fraction	0.59 ± 0.11	0.58 ± 0.11 (NS)	
Preoperative coronary score	11.3 ± 7.7	14.2 ± 7.2 ($p < 0.05$)	
Perioperative coronary score (all grafts assumed open)	1.1 ± 2.1	1.8 ± 3.0 (NS)	
No. of grafts placed	2.3 ± 0.8	2.3 ± 0.8 (NS)	
	Postoperative		
No. of recatheterizations	78	276	162
Follow-up after surgery (range, SD) (days)	688 days 20–1533, 425	1 year 271–776, 66	3 years 912–1462, 84
Postoperative coronary score			
Native coronary circulation	17 ± 9	19 ± 8 (NS)	22 ±9 ($p < 0.01$)
Corrected score (grafts in actual state)	9.2 ± 7.8	5.0 ± 5.7 ($p < 0.001$)	6.8 ± 7.5 ($p < 0.05$)
Corrected score (grafts assumed open)	2.7 ± 4.3	2.3 ± 3.6 (NS)	4.1 ± 4.9 (NS)
Patency rate grafts	55%	82% ($p < 0.0001$)	80% ($p < 0.0001$)

Values are mean + standard deviation.
p value: univariate statistics, unpaired *t* test, no symptoms vs symptoms.
NS = not significant; SD = standard deviation.

improved if adverse postoperative outcome could be predicted. Of the approximately 80 analyzed clinical, angiographic and perioperative variables, 3 variables were associated with clinical outcome, but classified outcome correctly in only 61% of all patients. This predictive value is too low to be clinically useful.

Explanatory factors for severe symptoms after bypass surgery: Postoperative angina pectoris is often related to incomplete revascularization, early closure of grafts or progression of coronary sclerosis in the native coronary arteries.[4,9–13] Adverse clinical outcome was associated with a higher attrition rate of grafts, whereas no differences were found in the rate of incomplete revascularization or progession of CAD in the native system of patients with no or mild symptoms compared with those who had severe symptoms. We do not know the reason for this higher graft closure rate in the symptomatic patients; although a low intraoperative graft flow, performance of endarterectomy and perioperative complications are associated with a higher graft attrition rate,[14] these findings do not imply that all these patients became severely symptomatic, as was the endpoint in this study.

Reoperability rate, management and clinical outcome of severely symptomatic patients: The reoperability rate of severely symptomatic patients was about 50%. In the remainder, coronary anatomy was unsuitable for further surgery. With intensive medical treatment, 50% of these patients improved to NYHA class I or II. Most of the reoperable patients were initially offered intense medical treatment before repeat surgery was advised; with such treatment about one-third of the patients improved to class I or II symptoms. The others underwent reoperation, after which 83% improved to class I, II or III.

Introducing TONOCARD®

(TOCAINIDE HCl | MSD)

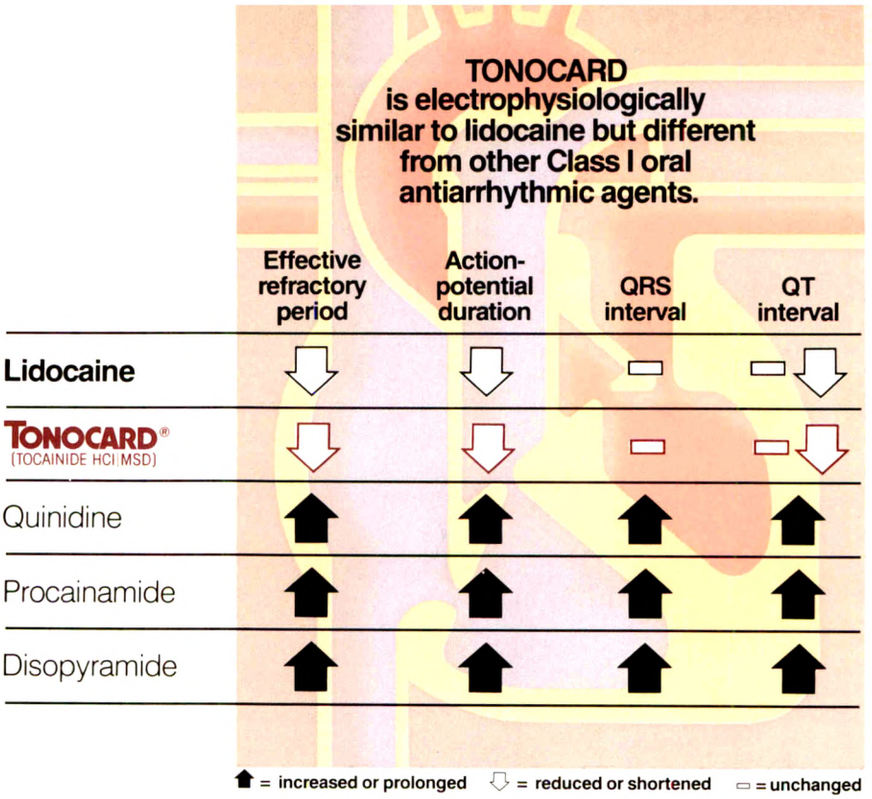
a new oral agent for the suppression of symptomatic ventricular arrhythmias

Like lidocaine.

But it's oral.

For a Brief Summary of Prescribing Information, please see last page of this advertisement.

MSD
MERCK SHARP & DOHME



Adapted from Braunwald, E.: Pharmacologic treatment of cardiovascular disorders, in *Harrison's Principles of Internal Medicine*, ed. K. J. Isselbacher et al., 9th ed., New York, McGraw-Hill Book Company, 1980, pp. 1068-1069. Data derived from animal and human studies.

☐ Patients who respond to lidocaine also respond to TONOCARD in a majority of cases. Failure to respond to lidocaine usually predicts failure to respond to TONOCARD, but there are exceptions.

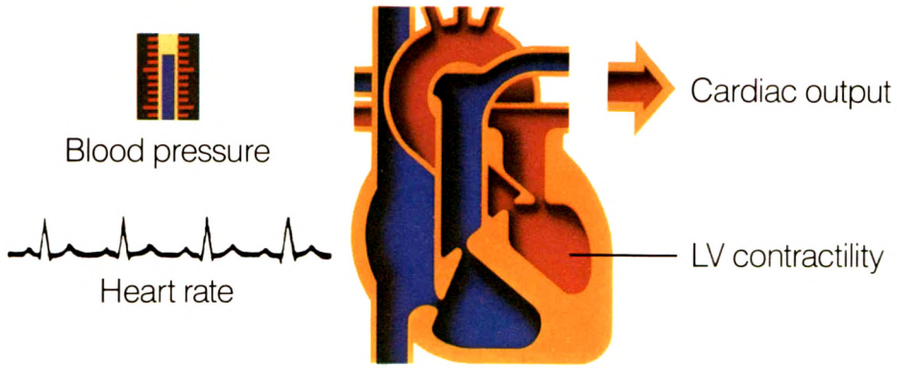
Therapeutically, it acts like lidocaine.

®Astra Pharmaceutical Products, Inc.

Copyright © 1984 by Merck & Co., Inc.

Clinical cardiac parameters were usually unchanged in well-compensated patients studied.

- In a long-term study of 72 post-myocardial infarction patients, TONOCARD (400 mg q 8 h) did not produce clinically significant changes in blood pressure, heart rate, or LV contractility.



- In catheterization studies, TONOCARD usually produced a small degree of depression in left ventricular function, but there were usually no changes in cardiac output or clinical evidence of increasing congestive heart failure.

TONOCARD has been used safely in patients with acute myocardial infarction and various degrees of congestive heart failure. It has, however, a small negative inotropic effect and can increase peripheral resistance slightly.

- TONOCARD should be used cautiously in patients with known heart failure or minimal cardiac reserve, particularly if a beta blocker is given as well, because of the potential for aggravating the degree of heart failure.

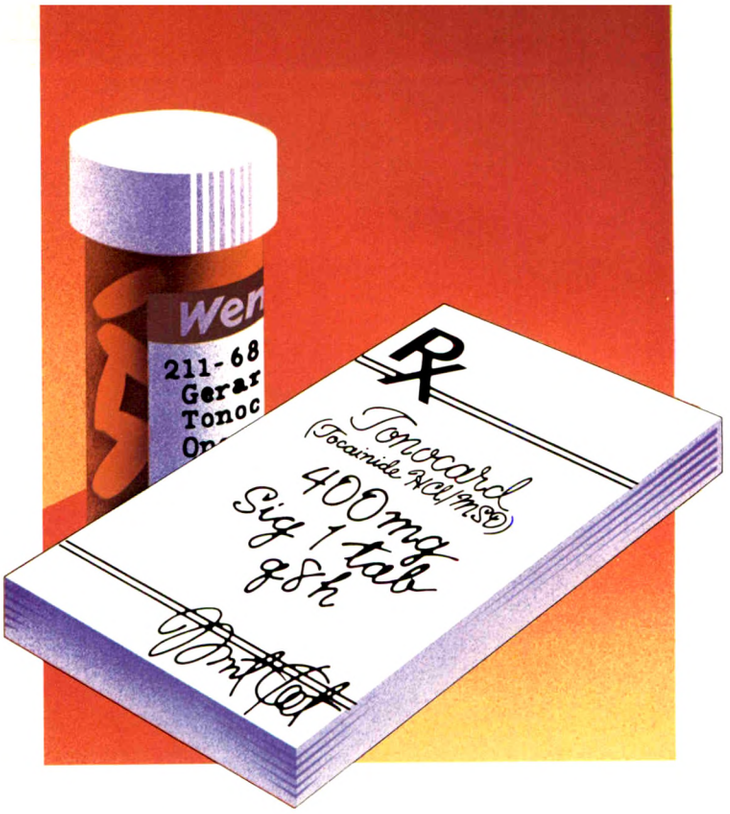
TONOCARD is contraindicated in patients who are hypersensitive to this product or to local anesthetics of the amide type and in patients with second- or third-degree atrioventricular block in the absence of an artificial ventricular pacemaker.

For a Brief Summary of Prescribing Information, please see last page of this advertisement.

But it's oral.

new
TONOCARD®
(TOCAINIDE HCl | MSD)

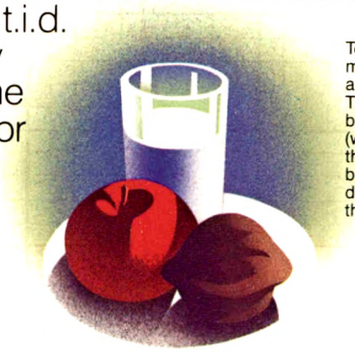
MSD
MERCK SHARP & DOHME



☐ Simple initial q 8 h dosage.

Unlike lidocaine, it's usefu for maintenance therapy.

Recommended initial dosage is 400 mg every 8 hours; patients should then be carefully titrated on the basis of antiarrhythmic response and tolerance, both of which are dose-related. The usual adult dosage is between 1200 and 1800 mg/day, divided in three doses. Doses beyond 2400 mg have been administered infrequently. Patients who tolerate the t.i.d. regimen may be tried on a twice-daily regimen with careful monitoring. Some patients, particularly those with renal or hepatic impairment, may be treated with less than 1200 mg/day.



To help alleviate the most common adverse reactions, TONOCARD may be given with food (without affecting the extent of its bioavailability), the dosage reduced, or therapy discontinued.

Like other antiarrhythmics, tocainide has not been shown to prevent sudden death in patients with serious ventricular ectopic activity, and also, like other antiarrhythmics, it has potentially serious adverse effects including the ability to worsen arrhythmias. It is therefore essential that each patient given tocainide be evaluated electrocardiographically and clinically prior to and during tocainide therapy to determine whether the response to tocainide supports continued treatment.

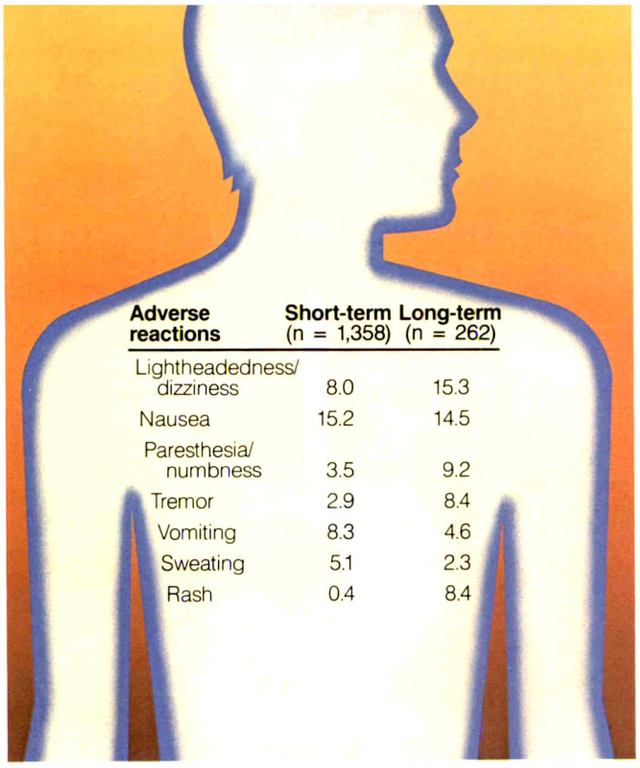
For a Brief Summary of Prescribing Information, please see last page of this advertisement.

Because it's oral.

new TONOCARD®

(TOCAINIDE HCl | MSD)

MSD
MERCK SHARP & DOHME



Reactions leading to therapy discontinuation occurred in 21% of patients in long-term (2 to 6 months) controlled trials.

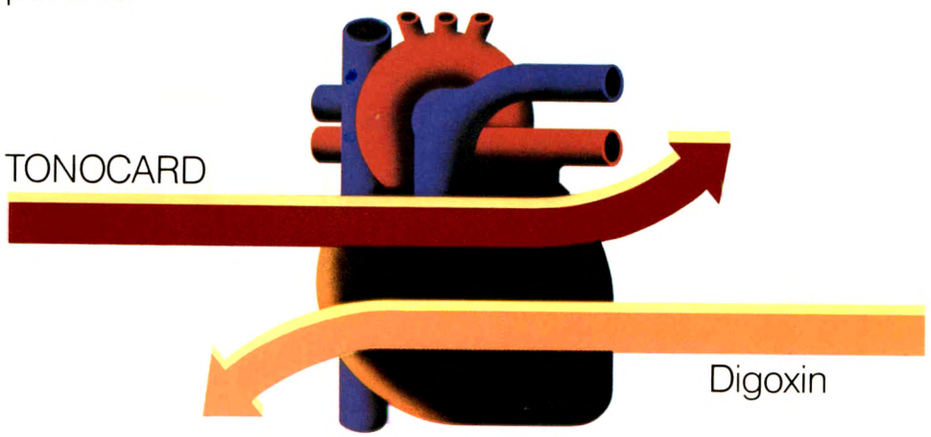
The most frequently reported adverse reactions, expressed as a percentage of patients receiving TONOCARD® (Tocainide HCl, MSD) in short-term and long-term controlled clinical trials.

- ☐ These adverse reactions were generally mild, transient, dose-related, and reversible with reduction in dosage, by taking the drug with food, or by therapy discontinuation.
- ☐ Tremor may be useful as a clinical indicator that the maximum dose is being approached.

CNS and GI reactions are common...

No interaction seen with digoxin.

- ☐ In specific interaction studies and open clinical studies with digoxin and TONOCARD, no clinically significant interaction was seen.
- ☐ TONOCARD is equally effective in digitalized and nondigitalized patients.



Other antiarrhythmics, anticoagulants, and diuretics were given with TONOCARD in open studies, without evidence of clinically significant interaction.

Beta blockers have been used with TONOCARD in open studies, without evidence of clinically significant interaction.

- ☐ However, in a specific interaction study, TONOCARD and metoprolol had additive effects on wedge pressure and cardiac index.

Caution should be exercised in the use of multiple-drug therapy.

Caution should be used in the institution or continuation of antiarrhythmic therapy in the presence of signs of increasing excessive depression of cardiac conductivity.

new **TONOCARD**®

(TOCAINIDE HCl | MSD)

MSD
MERCK

new TONOCARD®
(TOCAINIDE HCl | MSD)

An oral analog of lidocaine for the suppression of symptomatic ventricular arrhythmias

TONOCARD®
(Tocainide HCl | MSD)

Like other antiarrhythmics, tocainide has not been shown to prevent sudden death in patients with serious ventricular ectopic activity, and also, like other antiarrhythmics, it has potentially serious adverse effects, including the ability to worsen arrhythmias. It is therefore essential that each patient given tocainide be evaluated electrocardiographically and clinically prior to, and during, tocainide therapy to determine whether the response to tocainide supports continued treatment.

CONTRAINDICATIONS: Patients who are hypersensitive to this product or to local anesthetics of the amide type.

Patients with second or third degree atrioventricular block in the absence of an artificial ventricular pacemaker.

WARNINGS: ***Blood Dyscrasias:*** Leukopenia, agranulocytosis, hypoplastic anemia, and thrombocytopenia, possibly drug related, have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill and who were receiving concomitant drugs. Patients should be instructed to promptly report the development of bruising or bleeding and any signs of infection such as fever, sore throat, or chills. Periodic blood counts are recommended, particularly during the first six months of therapy. If any of these hematologic disorders is identified, TONOCARD should be discontinued and appropriate treatment should be instituted if necessary. Blood counts usually return to normal within one month of discontinuation (see ADVERSE REACTIONS).

Acceleration of Ventricular Rate. Acceleration of ventricular rate occurs infrequently when antiarrhythmics are administered to patients with atrial flutter or fibrillation (see ADVERSE REACTIONS).

PRECAUTIONS: *General* ***Pulmonary Fibrosis:*** Pulmonary fibrosis, pneumonitis, alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill. The experiences are usually characterized by bilateral infiltrates on x-ray and are frequently associated with dyspnea and cough. Fever may or may not be present. Patients should be instructed to promptly report the development of any pulmonary symptoms such as exertional dyspnea, cough or wheezing. Chest x-rays are advisable at that time. If these pulmonary disorders develop, TONOCARD should be discontinued (see ADVERSE REACTIONS).

In patients with known heart failure or minimal cardiac reserve, TONOCARD should be used with caution because of the potential for aggravating the degree of heart failure.

Caution should be used in the institution or continuation of antiarrhythmic therapy in the presence of signs of increasing depression of cardiac conductivity.

In patients with severe liver or kidney disease, the rate of drug elimination may be significantly decreased (see DOSAGE AND ADMINISTRATION).

Since antiarrhythmic drugs may be ineffective in patients with hypokalemia, the possibility of a potassium deficit should be explored and, if present, the deficit should be corrected.

Like all other oral antiarrhythmics, TONOCARD has been reported to increase arrhythmias in some patients (see ADVERSE REACTIONS).

Drug Interactions: Specific interaction studies with digoxin and metoprolol have been conducted; no clinically significant interaction was seen with digoxin, but tocainide and metoprolol had additive effects on wedge pressure and cardiac index. TONOCARD has also been used in open studies with digitalis, beta-blocking agents, other antiarrhythmic agents, anticoagulants, and diuretics, without evidence of clinically significant interactions. Nevertheless, caution should be exercised in the use of multiple drug therapy.

TONOCARD is equally effective in digitalized and nondigitalized patients. In 17 patients with refractory ventricular arrhythmias on concomitant therapy, serum digoxin levels (1.1 ± 0.4 ng/mL) remained in the expected normal range (0.5-2.5 ng/mL) during tocainide administration.

Pregnancy: Pregnancy Category C. In a teratogenicity study in rabbits, tocainide was administered orally at doses of 25, 50, and 100 mg/kg/day (about 1 to 4 times the usual human dose). No evidence of a drug-related teratogenic effect was noted; however, these doses were maternotoxic and produced a dose-related increase in abortions and stillbirths. In a teratogenicity study in rats, an oral dose of 300 mg/kg/day (about 12 times the usual human dose) showed no evidence of treatment-related fetal malformations, but maternotoxicity and an increase in fetal resorptions were noted. An oral dose of 30 mg/kg/day (about twice the usual human dose) did not produce any adverse effects.

In reproduction studies in rats at maternotoxic oral doses of 200 and 300 mg/kg/day (about 8 and 12 times the usual human dose, respectively), dystocia, and delayed parturition occurred which was accompanied by an increase in stillbirths and decreased survival in offspring during the first week postpartum. Growth and viability of surviving offspring were not affected for the remainder of the lactation period.

TONOCARD®
(Tocainide HCl | MSD)

There are no adequate and well-controlled studies in pregnant women. TONOCARD should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether tocainide is secreted in human milk. Because many drugs are secreted in human milk and because of the potential for serious adverse reactions in nursing infants from TONOCARD, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: TONOCARD commonly produces minor, transient, nervous system and gastrointestinal adverse reactions, but is otherwise generally well tolerated. TONOCARD has been evaluated in both short-term (n = 1,358) and long-term (n = 262) controlled studies as well as a compassionate use program. Dosages were lower in most of the controlled studies (1200 mg/day) and higher in the compassionate use program (1800 mg and more). In long-term (2-6 months) controlled studies, the most frequent adverse reactions were lightheadedness/dizziness (15.3 percent), nausea (14.5 percent), paresthesia/numbness (9.2 percent), and tremor (8.4 percent). These reactions were generally mild, transient, dose-related and reversible with a reduction in dosage, by taking the drug with food, or by therapy discontinuation. Tremor, when present, may be useful as a clinical indicator that the maximum dose is being approached. Adverse reactions leading to therapy discontinuation occurred in 21 percent of patients in long-term controlled trials and were usually related to the nervous system or gastrointestinal system.

Adverse reactions occurring in greater than one percent of patients from the short-term and long-term controlled studies appear in the following table:

	Percent of Patients Controlled Studies	
	Short-term (n = 1,358)	Long-term (n = 262)
NERVOUS SYSTEM		
Lightheadedness/dizziness/ vertigo/giddiness	8.0	15.3
Paresthesia/numbness	3.5	9.2
Tremor/quivering/tremulousness	2.9	8.4
Confusion/disorientation/ hallucinations	2.1	2.7
Altered mood/awareness	1.5	3.4
Restlessness/shakiness/ nervousness	1.5	0.4
Blurred vision/visual disturbances	1.3	1.5

Conduction disturbances	1.5	0.0
Left ventricular failure	1.4	0.0
OTHER		
Sweating/cold sweat/night sweats/ clammy	5.1	2.3
Headache	2.1	4.6
Tiredness/drowsiness/fatigue/ lethargy/lassitude/sleepiness	1.6	0.8
Hot/cold feelings	0.5	1.5
Rash/skin lesion	0.4	8.4

An additional group of about 2,000 patients has been treated in a program allowing for the use of TONOCARD under compassionate use circumstances. These patients were seriously ill with the large majority on multiple drug therapy, and comparatively high doses of TONOCARD were used. Fifty-four percent of the patients continued in the program for one year or longer, and 12 percent were treated for longer than three years, with the longest duration of therapy being nine years. Adverse reactions leading to therapy discontinuation occurred in 12 percent of patients (usually central nervous system effects or rash). A tabulation of adverse reactions occurring in one percent or more of patients follows:

TONOCARD®
(Tocainide HCl | MSD)

Adverse reactions occurring in less than one per tients in either the controlled studies or the comp use program are as follows:

Nervous System: Coma, convulsions/seizure sion, psychosis, mental change, agitation, altered difficulty concentrating, diplopia, dysarthria, impa ory, increased stuttering/slurred speech, insomni disturbance, local anesthesia, nightmares, thirst, myasthenia gravis.

Gastrointestinal System: Abdominal pain/c constipation, dysphagia, gastrointestinal symptoi ing dyspepsia).

Cardiovascular System: Ventricular fibrillation, of acute myocardial infarction, cardiogenic shock, block, hypertension, increased QRS duration, pl carditis, prolonged QT interval, right bundle bra syncope, vaso-vagal episodes, cardiomegaly, sinu

Pulmonary System: Respiratory arrest, pulmon pulmonary embolism, pulmonary fibrosis, alvec monia, pneumonitis, dyspnea.

Other: Hematologic disorder (agranulocyt plastic anemia, anemia, leukopenia, thrombocyt creased ANA, urinary retention, polyuria/increase alopecia, cinchonism, claudication, cold extrer mouth, earache, edema, fever, hiccups, itching, l malaise, metallic/menthol taste, muscle twitching/sp pain, pain radiating from neck, pallor/flushed face on shoulder, yawning.

Leukopenia, agranulocytosis, hypoplastic ar thrombocytopenia, possibly drug related, hav ported (0.10 percent) in patients receiving TON controlled trials and the compassionate use progr hematologic disorders usually occurred after 2-1 therapy and two patients died. These events usuall in seriously ill patients who were receiving concom known to be associated with hematologic disc WARNINGS).

Pulmonary fibrosis, pneumonitis, alveolitis, edema, and pneumonia, possibly drug related, reported in patients receiving TONOCARD. The of pulmonary fibrosis was 0.03 percent in conti and the compassionate use program. These eve occurred in seriously ill patients. Symptoms of th nary disorders and/or x-ray changes usually occu ing 3-18 weeks of therapy and two patients PRECAUTIONS).

HOW SUPPLIED: Tablets containing 400 mg or bottles of 100 and unit-dose packages of 100.

Usefulness of Electrophysiologic Testing in Evaluation of Amiodarone Therapy for Sustained Ventricular Tachyarrhythmias Associated with Coronary Heart Disease

LEONARD N. HOROWITZ, MD, ALLAN M. GREENSPAN, MD, SCOTT R. SPIELMAN, MD, CHARLES R. WEBB, MD, JOEL MORGANROTH, MD, HESCHI ROTMENSCH, MD, NEIL M. SOKOLOFF, MD, ALAN P. RAE, MD, BERNARD L. SEGAL, MD, and HAROLD R. KAY, MD

The prognostic importance of electrophysiologic studies in patients with sustained ventricular tachyarrhythmias treated with amiodarone was prospectively studied in 100 consecutive patients. Sustained ventricular tachycardia (VT)/ventricular fibrillation (VF) was inducible in all patients before amiodarone therapy. After amiodarone administration 2 groups of patients were identified. In group 1 patients the ventricular tachyarrhythmia was no longer inducible and in group 2 patients the arrhythmia remained inducible. In group 1, no recurrent arrhythmia occurred during a follow-up of 18 ± 10 months. In group 2, 38 of 80 patients (48%) had arrhythmia recurrence during a follow-up of 12 ± 9 months. The difference between group 1 and 2 could not be explained by clinical variables, amiodarone doses or plasma concentrations, or electrocardiographic variables. In patients in whom cardiovascular collapse or other severe symptoms where noted during electrophysiologic study after amiodarone treatment, recurrences caused sudden death (n = 12). However, in patients in whom the induced arrhythmia produced moderate symptoms, the recurrent arrhythmia was nonfatal VT (n = 26). Electrophysiologic testing provides clinical guidance and predicts prognosis in patients treated with amiodarone as it does for the evaluation of other antiarrhythmic agents.

(Am J Cardiol 1985;55:367–371)

The value of clinical electrophysiologic testing in the evaluation of amiodarone for the treatment of ventricular tachyarrhythmias has been controversial. It has been suggested that, unlike most other antiarrhythmic agents that have been extensively evaluated, the continued inducibility of a ventricular tachyarrhythmia during amiodarone therapy does not accurately predict subsequent clinical recurrences of arrhythmia. Therefore, some investigators recommend that amiodarone be used empirically in patients with even life-threatening ventricular tachyarrhythmias.[1–3] The present study was designed to prospectively assess the clinical value of electrophysiologic testing in patients with ventricular tachycardia (VT) ventricular fibrillation (VF), or both, treated with amiodarone.

From the Division of Clinical Cardiac Electrophysiology and the Computer Center of the Likoff Cardiovascular Institute, Hahnemann University Hospital and School of Medicine, Philadelphia, Pennsylvania. Manuscript received August 16, 1984; revised manuscript received October 4, 1984, accepted October 5, 1984.

Address for reprints: Leonard N. Horowitz, MD, Likoff Cardiovascular Institute, Hahnemann University and Hospital, Broad and Vine Street, Philadelphia, Pennsylvania 19102.

Methods

One hundred consecutive patients who had symptomatic sustained ventricular tachyarrhythmias complicating coronary artery disease (CAD) and who were treated with amiodarone were studied prospectively. To avoid biases that could confound analysis of the results, no patient's clinical management was altered by the results of the electrophysiologic evaluation and no additional antiarrhythmic interventions (pharmacologic or surgical) were undertaken in any patient until an arrhythmia recurred. By study design all patients who were started on amiodarone therapy continued unless side effects or arrhythmia recurrence caused an alteration or discontinuation of therapy. There were 86 men and 14 women, aged 38 to 78 years (mean 61). All patients had CAD, 97 of whom had had a myocardial infarction. The indication for electrophysiologic study was recurrent VT in 67 patients and cardiac arrest in 33. The left ventricular ejection fraction,

measured by radionuclide angiography, ranged from 8 to 52% (mean 25%).

In no patient was the spontaneous ventricular arrhythmia related to acute ischemia, metabolic or electrolyte abnormalities, or the proarrhythmic effects of drugs. Because this study was designed to evaluate the usefulness of electrophysiologic testing in the evaluation of amiodarone, only patients in whom sustained VT or VF was inducible in the baseline state were included in this study.

Before amiodarone treatment: All patients underwent an initial electrophysiologic study after all antiarrhythmic drugs had been discontinued for at least 5 half-lives. Their elimination was documented by plasma concentration measurement. Patients then underwent serial drug studies to evaluate the efficacy of standard and investigational agents in preventing initiation of VT or VF. The number of studies before amiodarone ranged from 0 to 7 (mean 2.6). Antiarrhythmic regimens tested before amiodarone included procainamide (76 patients), quinidine (55 patients), disopyramide (3 patients), mexiletine (48 patients), phenytoin (3 patients), the combination of procainamide or quinidine with mexiletine (51 patients), flecainide (6 patients), indecainide (7 patients) and bethanidine (2 patients). If no released or investigational agent or combination regimen prevented initiation of the arrhythmia or if the patient did not tolerate a regimen that did prevent initiation of ventricular tachyarrhythmia, amiodarone was selected for therapy.

Amiodarone administration: Amiodarone therapy was initiated with either an oral or an oral plus intravenous regimen. In the oral protocol, patients received 1,000 mg/day on days 1 through 7 and 800 mg/day on days 8 through 14. Electrophysiologic testing was performed on day 13, 14 or 15. In the oral-plus-intravenous protocol, patients received 10 mg/kg/24 hours of amiodarone by continuous intravenous infusion and 600 mg/day orally on days 1 through 3. The intravenous infusion was discontinued and the patients received 800 mg/day orally on days 4 through 10. Electrophysiologic testing was performed on day 9, 10 or 11 in this protocol.

In all cases, electrophysiologic testing was performed while the patient was receiving amiodarone as the only antiarrhythmic agent. If a hemodynamically significant, symptomatic ventricular tachyarrhythmia remained inducible, procainamide or quinidine was added and electrophysiologic testing was repeated unless contraindicated by clinical history or other factors. A beneficial response to the combination regimen was either inability to initiate the arrhythmia, or if the VT remained inducible, it was slower and less symptomatic.

Electrophysiologic protocol and definitions: The same stimulation protocol was used in every study. This included the introduction of 1, 2 and 3 ventricular extrastimuli during sinus rhythm and ventricular pacing at cycle lengths of 600 and 450 ms. The stimulus was a rectangular impulse (1 ms in duration) delivered at twice diastolic threshold. Stimulation was performed at the right ventricular apex in all patients, and if no arrhythmia was induced, then at the right ventricular outflow tract. Left ventricular stimulation was performed only in the initial study if an arrhythmia was not inducible with with right ventricular stimulation (3 patients). Left ventricular stimulation at 2 sites was repeated at the amiodarone study only when left ventricular stimulation was required during the initial study. The stimulation protocol was terminated only at the initiation of sustained VT or VF. If nonsustained VT was initiated, stimulation was continued until initiation of a sustained VT or VF or completion of the stimulation protocol.

Responses to stimulation during the baseline study were categorized as: (1) Sustained VT, defined as a tachycardia which lasted more than 30 seconds or required termination within 30 seconds because of hemodynamically significant symptoms. (2) VF, defined as the induced rhythm when, within 3 seconds of the initiation of a sustained ventricular tachyarrhythmia, the surface electrocardiogram showed VF. If a tachyarrhythmia remained organized for more than 3 seconds it was termed VT even if it subsequently spontaneously degenerated to VF.

An arrhythmia was defined as *inducible* after amiodarone if VT or VF was initiated by any part of the complete stimulation protocol delivered to both the right ventricular apex and right ventricular outflow tract regardless of the mode of stimulation that initiated the tachyarrhythmia before amiodarone. An arrhythmia was considered *not inducible* after amiodarone if fewer than 16 complexes of VT were initiated using the complete stimulation protocol delivered to both the right ventricular apex and right ventricular outflow tract.[4]

Symptoms during the VT/VF induced at the postamiodarone study were classified as severe if the arrhythmia produced cardiovascular collapse, severe angina or near syncope. The symptoms were not severe if lightheadedness, palpitations or transient dizziness occurred.

Antiarrhythmic medications and follow-up: All patients were discharged on amiodarone, 600 mg/day. This dose was reduced to 400 mg after 4 months in all patients continuing to receive medication at that point. In 8 patients the dose was subsequently reduced to less than 400 mg because of the development of side effects. An additional antiarrhythmic drug was used in 13 patients based on the results of electrophysiologic testing. Patients were followed in a research arrhythmia clinic and were seen 1 month after discharge, every 4 months during the first year, and every 6 months thereafter. Holter monitor recordings were obtained at each clinic visit. Active attempts were made to obtain electrocardiographic documentation of any symptomatic episode compatible with recurrent arrhythmia using Holter monitoring, transtelephonic electrocardiographic transmissions and in-hospital telemetric monitoring.

Sudden death or electrocardiographically documented symptomatic VT occurring more than 1 month after starting amiodarone were classified as recurrent arrhythmia. Sudden cardiac death was defined as an unexpected, witnessed death occurring within 1 hour of the onset of symptoms and a catastrophic change in the state of health that could not be explained by obvious causes. If the death was not witnessed the patient must have been seen within the previous 12 hours and been free of chest pain. If a patient was resuscitated from an arrhythmic event, that event was considered a sudden cardiac death for statistical purposes. Nonarrhythmic cardiac death was caused by progressive congestive heart failure or myocardial infarction. Since there are many potential causes for syncope in this patient population, we did not consider the occurrence of syncope from which the patient recovered without resuscitation or bystander assistance and in whom no electrocardiographic documentation of recurrent VT was obtained, to be the result of recurrent VT.

The duration of follow-up was calculated from the date amiodarone was started to either the time of first arrhythmia recurrence (38 patients), death (9 patients), discontinuation of amiodarone because of side effects (9 patients) or September 1, 1984 (44 patients).

Statistical methods: Standard life-table analysis techniques[5] were used to summarize results. The response variable was recurrence of the arrhythmia. Patients in whom amiodarone side effects caused drug discontinuation were considered censored as of the date of discontinuation. Patients who died without documented recurrence (i.e., patients who died from nonarrhythmic causes) were considered censored

as of the date of death. Patients who died suddenly were considered to have had a recurrence as of the date of death. No patient was lost to follow-up. The Mantel-Cox and Breslow statistics were used to test the equality of survival curves.

Contingency table analyses were calculated using either chi-square or Fisher's exact tests. A Student t test and analysis of variance techniques were used to test for intergroup differences. A p value <0.05 was considered significant.

Results

All 100 patients in this study had sustained VT or VF inducible at the initial electrophysiologic study. Monomorphic VT was inducible in 95 patients and VF was inducible in 5 patients. After amiodarone loading, 2 groups of patients were identified by electrophysiologic testing: In group 1 patients, the tachyarrhythmia was no longer inducible and in group 2 patients, it remained inducible.

Group 1 consisted of 20 patients. The induced arrhythmias before amiodarone treatment in this group included VT in 18 patients and VF in 2 patients. In 18 patients, noninducibility was achieved with amiodarone alone and in 2 patients the combination of amiodarone and procainamide produced a noninducible response. All patients were treated with the regimen that produced a noninducible response. Follow-up in group 1 ranged from 4 to 31 months (mean 18). Except for 1 patient, who died of myocardial infarction 4 months after starting amiodarone therapy, the minimum follow-up in this group was 12 months. There were no recurrent symptomatic VT or VF and no sudden deaths in this group. Two patients died of nonarrhythmic cardiac causes. Amiodarone was discontinued because of side effects in 3 patients.

Group 2 consisted of 80 patients. The amiodarone induced arrhythmias before amiodarone treatment were VT (77 patients) and VF (3 patients). After amiodarone treatment, sustained VT was induced in 76 patients, VF in 2 patients and nonsustained VT in 2 patients. Amiodarone alone was used in 69 patients, and 11 patients were treated with amiodarone in combination with either procainamide (7 patients) or quinidine (4 patients). Follow-up in group 2 ranged from 2 to 32 months (mean 12). Symptomatic VT or VF recurred in 38 of 80 patients (48%). Seven patients died from nonarrhythmic cardiac causes in group 2. Amiodarone was discontinued because of toxicity in 6 patients.

The recurrent VT or VF occurred between 1 and 3 months after hospital discharge in 20 patients and between 3 and 18 months after discharge in 18 patients. The dose of amiodarone at the time of recurrence was 600 mg/day in 21 patients, 400 mg/day in 14 and less than 400 mg/day in 3.

The difference in recurrence-free interval between groups 1 and 2 was highly significant using either the Breslow and Mantel-Cox analyses (Fig. 1). Groups 1 and 2 were not significantly different with respect to baseline ventricular tachyarrhythmia, ejection fraction (25 vs 24%), age or severity of heart disease.

The amiodarone doses and plasma concentrations were analyzed using 2-way analysis of variance techniques to ascertain whether differences in these parameters could explain the difference between groups 1 and 2. There were no differences between group 1 and 2 in amiodarone plasma concentrations at the time of electrophysiologic study or during follow-up (Table I). Similarly, there was no significant difference during follow-up in amiodarone dose (391 [range 243 to 400] vs 432 [range 300 to 600] mg/day) or QTc interval (462 [range 350 to 520] vs 471 [range 380 to 580] ms) between groups 1 and 2.

TABLE I Comparison of Mean Amiodarone Plasma Levels (mg/liter) by Group and Time of Measurement

	Group I Noninducible (n = 11)	Group II Inducible (n = 69)
Time of measurement electrophysiologic study	1.41	1.71
Follow-up level*	1.77	2.06
Analysis of Variance Table		
Effect on amiodarone level	F	p
Group (I or II)	2.23	0.14
Time of measurement	3.19	0.08
Interation	0.00	0.96

* Follow-up level is either the last measured amiodarone plasma level before recurrence or the most recently measured amiodarone plasma level in patients without recurrence.

Two subgroups of patients (those with and those without recurrence) whose VT/VF remained inducible were analyzed in a similar fashion. There was no significant difference in amiodarone plasma concentrations between the subgroups (2.2 [range 0.7 to 3.8] vs 1.9 [range 0.5 to 3.5] mg/liter). Amiodarone dose in the recurrence-free subgroup was significantly lower than in the group with recurrent VT/VF (391 ± 91 vs 499 ± 110 mg/day, p <0.0001). The QTc interval in the 2 subgroups was not different (475 [recurrence] vs 457 [no

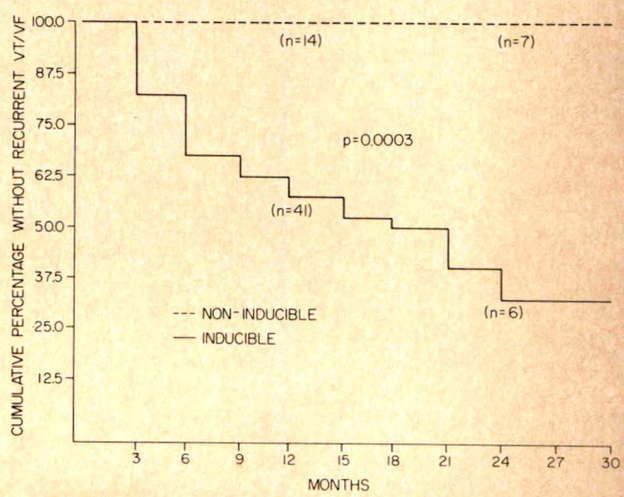

FIGURE 1. Life-table analysis of results in patients with and without inducible ventricular tachycardia/ventricular fibrillation (VT/VF) during amiodarone therapy. By 18 months, approximately 50% of patients with inducible VT/VF had a recurrence. The numbers in parentheses indicate the number of patients who remained available for analysis.

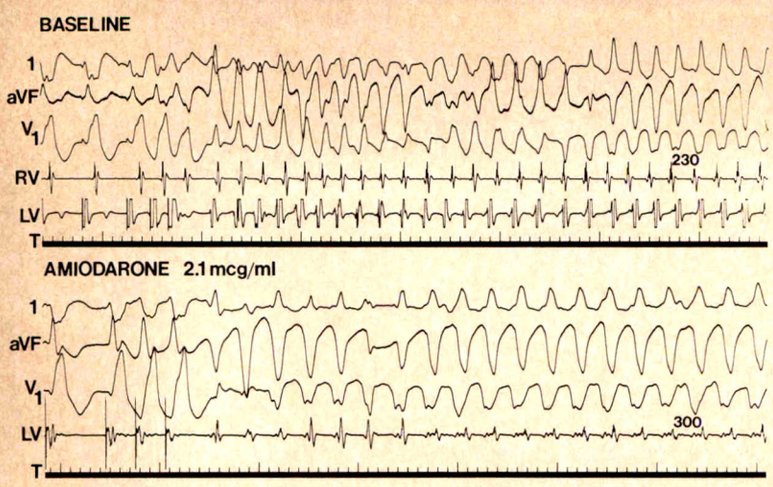

FIGURE 2. Electrophysiologic study in a patient who subsequently died suddenly. Electrocardiographic leads 1, aVF and V_1 are shown with right ventricular apical (RV) and left ventricular lateral wall (LV) intracardiac electrograms and 100-ms time marks (T). The pretreatment (BASELINE) study is shown in the **top** panel. Programmed stimulation initiated a uniform-morphology ventricular tachycardia (VT) (cycle length 230 ms) that produced syncope. Cardioversion was required for termination. After amiodarone loading, programmed stimulation initiated a slower VT (cycle length 300 ms) of similar morphology. This VT also produced syncope and cardioversion was required. This patient died suddenly 5 months after initiation of amiodarone therapy.

recurrence] ms). Other factors including baseline QTc, change in QTc, baseline and change in ventricular effective refractory period, and baseline and change in VT cycle length were analyzed and were not different between the subgroups.

Analysis of the arrhythmia recurrences within group 2 provided further evidence for the utility of electrophysiologic testing of amiodarone therapy. Of the 80 patients in whom the arrhythmia was inducible, 24 had severe symptoms (such as cardiovascular collapse) during their induced VT/VF after amiodarone loading; 12 (50%) subsequently died suddenly (Fig. 2). In each the induced VT/VF was sustained. In 8 it required cardioversion; in 4 it produced severe angina and near syncope before termination by pacing.

Fifty-six patients had inducible VT that did not produce severe symptoms. Twenty-six patients (46%) had a recurrence and none were fatal. Sustained VT was the arrhythmia induced after amiodarone loading in all 26 patients (Fig. 3). The VT cycle lengths were significantly shorter in the patients with severe symptoms during induced VT (304 [range 250 to 320] vs 411 [range 300 to 580] ms, $p = 0.005$).

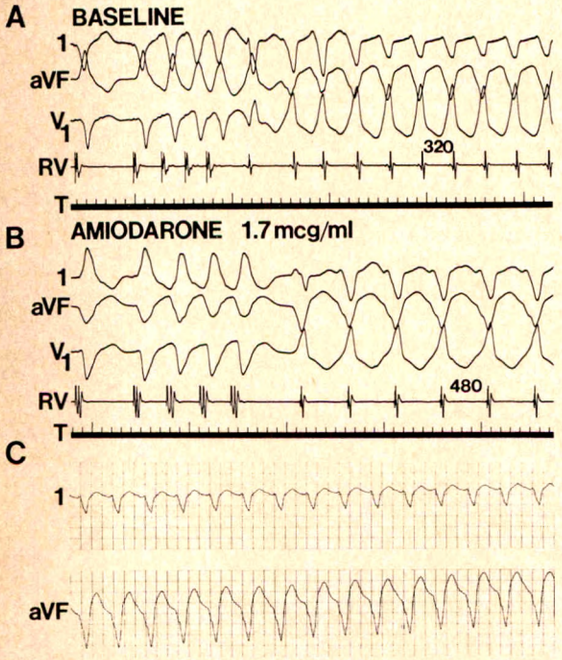

FIGURE 3. Electrophysiologic study and recurrent spontaneous ventricular tachycardia (VT) in a patient treated with amiodarone. **A** and **B,** electrocardiographic leads 1, aVF and V_1 with a right ventricular electrogram (RV) and 100-ms time marks (T). **C,** simultaneously recorded leads 1 and aVF are shown during spontaneous VT. **A,** during the pretreatment (BASELINE) study, VT (cycle length 320 ms) was induced with triple extrastimuli. **B,** after amiodarone loading, the VT was still inducible, although it was considerably slower (cycle length 480 ms). The VT induced during the posttreatment study produced palpations. **C,** electrocardiogram recorded during a spontaneous recurrence of VT during which the patient reported "mild rapid heart action."

Discussion

We have shown that electrophysiologic testing is useful in identifying patients at risk of recurrent VT/VF during amiodarone therapy. More important, those patients in whom adjunctive therapy with drugs, devices or surgery are indicated can also be identified.

The predictive value of electrophysiologic testing of antiarrhythmic regimens when applied to conventional antiarrhythmic drugs has been excellent.[4,6–8] The recurrence rates of VT/VF are high (> 75%) in patients treated with antiarrhythmic regimens which fail to prevent initiation of VT/VF during electrophysiologic testing. There is a consensus that this type of evaluation is effective and indicated in patients with life-threatening arrhythmias.[9,10] With regard to amiodarone, however, no such consensus exists.

Several early reports suggested that electrophysiologic testing might not be useful in the evaluation of amiodarone.[1–3,11,12] Hamer and et al[1] reported that although they induced VT in 8 of 9 patients during amiodarone treatment, no patient suffered recurrent VT. They suggested that the efficacy of amiodarone in patients with VT may not be reliably predicted by electrophysiologic studies. Subsequent studies by others appear to support this impression.[13–15] The conclusion of these reports was that the recurrence rate of VT/VF in patients treated with amiodarone was very low, and

although VT continued to be inducible, recurrence rates could not be attributed to this continued inducibility.

Other groups have reported conflicting results. McGovern and Ruskin[16] reported 30 patients in whom electrophysiologic studies were performed before and after amiodarone therapy was initiated. Of patients in whom VT was either no longer inducible or more difficult to initiate after amiodarone treatment, 16 patients were free of recurrent VT, whereas in 14 patients in whom amiodarone had no effect on arrhythmia inducibility, 8 (57%) had recurrent VT/VF within 28 months. Borggrefe et al[17] presented results similar to those of the present study in a group of 36 patients. In this study 8 of 23 patients (34%) whose arrhythmia remained inducible during amiodarone treatment had recurrent VT/VF, whereas none had recurrent arrhythmia when the arrhythmia was more difficult or impossible to induce during amiodarone treatment.

The difference in conclusions between these 2 groups of studies may be accounted for by several variables. Significant differences are apparent in study design, stimulation protocols, methods for assessing and adjusting therapy, loading and maintenance regimens and the duration of follow-up. These disparities may account for the differing conclusions.

The present study was performed prospectively with an unaltered protocol over the 3 years, during which patients were enrolled and data collected. No additional antiarrhythmic interventions were undertaken in any patient who had not had a recurrence of arrhythmia (an endpoint of the study). Finally, no patient's clinical management was altered by the results of this evaluation to avoid a bias toward following only "less ill" patients. The results of this study were not influenced by amiodarone dose or plasma concentration, and there were no apparent differences between patient groups with respect to the effects of amiodarone (such as QTc and change in VT cycle length). A regimen was used that was well tolerated by most patients and thus was clinically applicable for chronic antiarrhythmic therapy in a large population of patients with CAD and depressed left ventricular function.

Our data show a correlation between the results of electrophysiologic testing and subsequent clinical outcome in patients with life-threatening VT/VF treated with amiodarone. Furthermore, we have shown that such testing predicts the severity of recurrent ventricular tachyarrhythmias when they do occur. This information may be used prospectively to implement adjunctive antiarrhythmic therapy, such as antiarrhythmic devices or surgery in patients who were at risk of suffering sudden death.

For patients with inducible but slow and minimally symptomatic VT, a clinical trial of amiodarone is acceptable. However, in patients with a rapid VT on amiodarone, alternate forms of therapy should be explored because the almost 50% recurrence rate is unacceptably high for a life-threatening situation. We propose that electrophysiologic testing be used for the clinical management of patients with lethal arrhythmias treated with amiodarone. The contention that most patients treated with amiodarone for ventricular tachyarrhythmias will not have a recurrence is not supported by the data. An assessment of prognosis and the severity of the potential recurrence is critical for management. Amiodarone is an effective antiarrhythmic agent but it should be evaluated by electrophysiologic techniques, as are other agents, in patients with lethal ventricular arrhythmias.

Cardiac Arrest and Sudden Death in Patients Treated with Amiodarone for Sustained Ventricular Tachycardia or Ventricular Fibrillation: Risk Stratification Based on Clinical Variables

LORENZO A. DICARLO, Jr., MD, FRED MORADY, MD, MARY JANE SAUVE, RN, MS, PATRICIA MALONE, RN, BS, JESSE C. DAVIS, MD, THOMAS EVANS-BELL, MD, STUART A. WINSTON, DO, and MELVIN M. SCHEINMAN, MD

Multivariate analysis of 11 clinical variables was performed in 104 patients with sustained, symptomatic ventricular tachycardia (VT) or ventricular fibrillation treated with amiodarone to determine variables predictive of subsequent cardiac arrest or sudden death. Twenty-five patients (24%) had fatal or nonfatal cardiac arrest after 7.3 ± 6.2 months (mean ± standard deviation) of therapy. Multivariate analysis identified an ejection fraction of less than 0.40, syncope or cardiac arrest before amiodarone therapy, and VT (3 or more consecutive ventricular premature complexes) during predischarge ambulatory electrocardiographic monitoring as variables associated with a high risk of subsequent fatal or nonfatal cardiac arrest ($p < 0.03$). Patients who had these 3 clinical variables had a much higher predicted incidence of cardiac arrest at 6 months (62%) and 12 months (76%) than did patients with an ejection fraction greater than 0.40, without syncope or cardiac arrest before amiodarone therapy, and without VT during predischarge ambulatory electrocardiographic monitoring (2% and 5%, respectively) ($p < 0.02$). Risk stratification using clinical variables can predict which patients are at high risk of recurrent cardiac arrest or sudden death during amiodarone therapy.

(Am J Cardiol 1985;55:372–374)

Patients who survive a cardiac arrest or who have recurrent, sustained ventricular tachycardia (VT) not controlled by conventional antiarrhythmic agents are at high risk of sudden death. Amiodarone has been reported to be effective in preventing recurrent VT or sudden death in 52 to 90% of these patients during mean follow-up periods of 8.6 to 21 months.[1–15] Clinical variables that predict which patients will benefit from long-term treatment with amiodarone are not known. Identification of patients who will have recurrent VT or ventricular fibrillation (VF) while being treated with amiodarone would allow selection of patients who might benefit from alternative forms of therapy, such as implantation of an automatic defibrillator, cardiac electrosurgery or use of other pharmacologic therapy. In this study, multiple clinical variables were analyzed in a group of 104 patients with recurrent VT or previous cardiac arrest to determine whether subgroups of patients at high risk of having recurrent VT or cardiac arrest during chronic amiodarone therapy could be identified.

Methods

One hundred four consecutive patients with sustained, symptomatic VT or VF treated with amiodarone were included in this study. Sustained VT was defined as VT at least 30 seconds in duration or requiring direct-current cardioversion for termination. Before treatment with amiodarone, each patient had had 1 or more episodes of spontaneous VT or VF, and either a spontaneous recurrence of VT or VF despite therapy with 1 or more conventional antiarrhythmic agents (53 patients), or inducible VT during electropharmacologic testing with 1 or more conventional antiarrhythmic agents (51 patients). Patients with VT or VF occurring within the first 48 hours of an acute myocardial infarction were excluded. Patients with VT or VF due to electrolyte or metabolic

abnormalities, antiarrhythmic therapy or other remediable causes were also excluded.

All patients underwent 24 hours of continuous ambulatory electrocardiographic (ECG) monitoring before hospital discharge, after 6 to 10 days of amiodarone therapy. The ambulatory ECG cassette recordings were analyzed using a microprocessor-based, automated arrhythmia detection and analysis system (Instruments for Cardiac Research, Inc., model 6201). Ambulatory recordings were analyzed for frequency and morphologic pattern of ventricular premature complexes (VPCs). Thirty or more VPCs/hour were considered frequent, and fewer than 30 VPCs/hour were considered infrequent. Ventricular tachycardia was defined as 3 or more consecutive VPCs.

The patient's clinical characteristics are listed in Table I. Left ventricular ejection fraction was determined in 61 patients by contrast or radionuclide ventriculography and by 2-dimensional echocardiography in 26 patients.

Amiodarone therapy: Amiodarone was administered in oral doses of 800 to 1,600 mg/day for 5 to 14 days before hospital discharge. In patients with a history of frequent episodes of VT or cardiac arrest, intravenous amiodarone was administered as a continuous infusion of 1 g over 24 hours for 1 to 5 days before initiation of oral therapy. After discharge, amiodarone was continued for 2 months at a dose of 800 mg/day, followed by a maintenance dose of 600 mg/day. Further dose adjustments depended on the occurrence of adverse effects and clinical response. In patients with a history of cardiac arrest, a conventional type I agent (usually procainamide or quinidine) was added and discontinued after 6 to 8 weeks.

Follow-up: The minimal follow-up period in patients who did not have a recurrence of VT or VF was 6 months. Follow-up data were collected by personal interview or by telephone or mail contact with all patients and referring physicians. All recurrences of VT were documented by ambulatory ECG recordings or by ECG rhythm strips. A recurrence of VT was defined as symptomatic, sustained VT after at least 2 weeks of amiodarone therapy. Cardiac arrest was defined as loss of consciousness due to VT or VF requiring cardiopulmonary resuscitation and direct-current cardioversion or defibrillation. Sudden death was defined as unexpected death of natural causes occurring during sleep or within 1 hour of the patient's collapse. Amiodarone was discontinued because of an adverse drug reaction in 10 patients, and because of noncompliance in 3 others; these patients were included in the analysis up to the point of discontinuation of amiodarone therapy. Patients who died from nonarrhythmic causes were included in the analysis as survivors until the times of their deaths.

Statistical analysis: The following variables were evaluated: age, gender, presence of previous myocardial infarction, infarct location, presence of a ventricular aneurysm, aneurysm location, ejection fraction, New York Heart Association class, symptoms associated with VT or VF (palpitations, syncope, in-hospital cardiac arrest, out-of-hospital cardiac arrest), digitalis therapy, and the results of predischarge ambulatory ECG monitoring. Multivariate analysis was performed with the Cox regression.

TABLE I Clinical Characteristics of 104 Patients Treated with Amiodarone

Age (yr)	61 ± 13*
Males/females	81/23
Heart disease	
Coronary artery disease	82 (79%)
Remote MI (>6 weeks)	65 (79%)
Recent MI (≤6 weeks)	9 (11%)

† Determined in 87 patients (84%).
CHF = congestive heart failure; MI = myocardial infarction; NYHA = New York Heart Association functional class.

Results

Results of therapy: During a follow-up period of 15.7 ± 9.1 months (mean ± standard deviation), 63 patients (61%) had no recurrence of symptomatic, sustained VT, cardiac arrest or sudden death; their mean amiodarone dose was 442 ± 160 mg/day. Twenty-five patients (24%) had a cardiac arrest due to VT or VF, or sudden death, after 7.3 ± 6.2 months of amiodarone therapy (mean dose 567 ± 183 mg/day). Five patients in this group were successfully resuscitated. Sixteen of the 104 patients (15%) had a recurrence of symptomatic VT without cardiac arrest or sudden death after 8.7 ± 8.1 months of therapy with a mean dose of 513 ± 219 mg/day. There was no significant difference in the incidence of cardiac arrest or sudden death during the first 2 months of follow-up when patients who received adjunctive therapy with a type I antiarrhythmic agent were compared with those who did not.

Results of multivariate analysis: Three variables were identified as predictive of cardiac arrest during amiodarone therapy: ejection fraction less than 0.40 ($p < 0.03$), the occurrence of syncope or cardiac arrest before amiodarone therapy ($p < 0.01$), and the presence of VT on the predischarge ambulatory electrocardiogram ($p < 0.03$). The cumulative effect of these 3 variables on predicted survival is illustrated in Figure 1. Patients in the subgroup who had an ejection fraction of 0.40 or greater, no previous syncope or cardiac arrest, and no VT during predischarge ambulatory ECG monitoring were predicted to have a survival rate of 98% at 6 months and 95% at 18 months. Patients with an ejection fraction less than 0.40, previous syncope or cardiac arrest, and VT during predischarge ambulatory monitoring had a predicted survival of 38% at 6 months and 24% at 18 months. Intermediate survival rates were predicted for patients having any 1 or any 2 of the 3 variables predictive of poor outcome.

Discussion

The prognosis of patients treated with amiodarone after resuscitation from cardiac arrest has varied widely. Previous studies have reported survival rates of 85 to 97% during mean follow-up periods of 12 to 19 months.[9,10,14,16] Differences in length of follow-up and clinical characteristics of the patients in each study group may account for the different survival rates. The

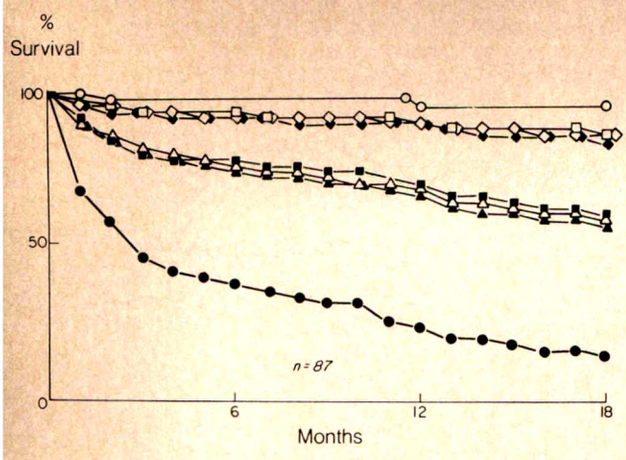

FIGURE 1. Cumulative effects of ejection fraction (EF), previous syncope or cardiac arrest (SYN/CA), and ventricular tachycardia (VT) during predischarge ambulatory electrocardiographic monitoring on predicted survival during amiodarone therapy EF ≥40, no SYN/CA, no VT (○); EF <40, no SYN/CA, no VT (□); EF ≥40, no SYN/CA, VT (◇); EF ≥40, SYN/CA, no VT (♦); EF <40, no SYN/CA, VT (■); EF <40, SYN/CA, no VT (△); EF ≥40, SYN/CA, VT (▲); EF <40, SYN/CA, VT (●). Statistical significance: EF, $p < 0.03$; SYN/CA, $p < 0.01$; VT $p < 0.03$.

results of our study suggest that patients treated with amiodarone can be stratified into subgroups at various degrees of risk for a poor clinical response. Multivariate analysis identified 3 variables associated with a high risk of cardiac arrest or sudden death: ejection fraction less than 0.40, syncope or cardiac arrest before amiodarone therapy, and VT during predischarge ambulatory ECG monitoring. In this series, the predicted survival of patients who had these 3 variables was only 24% after 18 months of amiodarone therapy.

The following limitations require that the results of this study be examined with caution: (1) In our study, frequency of VPCs was classified qualitatively as frequent or infrequent. Frequency of quantitative VPCs may still have significant importance as a predictor of subsequent fatal and nonfatal events[15–18] not identified by this study. However, a consistent correlation has not been shown.[4,15–18] (2) Ejection fraction in 26 patients (30%) was determined by 2 dimensional echocardiography. Although this technique provides an objective measurement of left ventricular function, it is not as accurate as contrast or radionuclide ventriculography.[19]

Results of Late Programmed Electrical Stimulation and Long-Term Electrophysiologic Effects of Amiodarone Therapy in Patients with Refractory Ventricular Tachycardia

ENRICO P. VELTRI, MD, PHILIP R. REID, MD, EDWARD V. PLATIA, MD, and LAWRENCE S.C. GRIFFITH, MD

Thirteen patients with refractory, recurrent, life-threatening ventricular tachycardia (VT) underwent electrophysiologic testing before and after long-term amiodarone therapy. Nine patients (69%) had coronary artery disease, 3 (23%) had nonischemic cardiomyopathy and 1 patient (8%) had mitral valve prolapse. At control electrophysiologic study, programmed electrical stimulation (PES) induced VT in all patients: sustained VT in 11 and nonsustained VT in 2 (9 beats and 31 beats). After oral loading with amiodarone, 1200 mg/day for 14 days, followed by maintenance therapy with 408 ± 20 mg/day (mean ± standard error of the mean), repeat PES at 6 ± 1.6 months revealed inducible VT in 12 of 13 patients: sustained VT in 11 and nonsustained VT (32 beats) in 1 patient. Inducible VT was suppressed in only 1 patient. Amiodarone significantly increased sinus cycle length, PR interval, QRS duration and right ventricular effective refractory period. Insignificant increases in AH, HV and QTc intervals were noted. At 24 ± 2 months, 8 patients (62%) (all with inducible VT at late PES) were free of clinical arrhythmic events (syncope or sudden death), compared with 5 patients (38%) (4 with inducible VT at late PES) with events. There were no significant differences in the induced VT cycle length, VT cycle length change, ease of inducibility or hemodynamic response to induced VT at late PES in patients with and without arrhythmic events. Thus, in patients who receive long-term amiodarone treatment, late PES does not predict clinical efficacy, the frequency of conversion from inducible VT to noninducible VT is low, and despite ventricular electrical instability as judged by late PES testing, amiodarone is clinically effective in patients at high risk.

(Am J Cardiol 1985;55:375–379)

Amiodarone, a benzofuran derivative originally developed as an antianginal agent[1] and subsequently found to have potent antiarrhythmic properties,[2–4] is effective in ventricular tachyarrhythmias.[5–17] Many studies have revealed a disparity in clinical and electrophysiologic efficacy[12–15,18–21]; others suggest a predictive role of programmed electrical stimulation (PES) in patients with ventricular tachycardia (VT) treated with amiodarone.[22–24]

The discrepancies among previously reported PES studies (which, for the most part, were performed within 1 to 2 months of starting amiodarone therapy) as well as the unusual pharmacokinetic profile of the drug, namely an estimated half-life of many weeks,[25,26] prompted the investigation of the role of late (after 6 weeks) PES testing in predicting long-term clinical efficacy and the electrophysiologic effect of chronic amiodarone therapy.

Methods

Patients: Thirteen patients (12 men, 1 woman) were referred to the Arrhythmia Service for the electrophysiologic evaluation of recurrent, life-threatening VT. Table I is a summary of the clinical characteristics. The mean age (± standard error of the mean) was 59 ± 4 years (range 22 to 74). All patients had at least 1 episode of documented sustained VT (mean 3.5). Twelve patients had 2 or more episodes within 1 year of referral. The clinical presentations were sudden death (cardiovascular collapse within 1 hour of symptoms requiring cardiopulmonary resuscitation or cardioversion from VT/ventricular fibrillation in the absence of acute myocardial infarction) in 9, syncope (transient loss of consciousness with spontaneous recovery) in 3, and presyn-

CAD = coronary artery disease; CCM = congestive cardiomyopathy; MI = myocardial infarction; MVP = mitral valve prolapse.

cope (light-headedness accompanying the arrhythmia) in 1 patient.

The underlying cardiac substrate, determined by cardiac catheterization and echocardiography, was coronary artery disease (defined by at least 70% coronary artery narrowing) in 9 patients (69%), nonischemic congestive cardiomyopathy (defined by diffuse left ventricular [LV] dysfunction with ejection fraction [EF] of 40% or less) in 3 patients (23%), and mitral valve prolapse in 1 patient (8%). Mean EF was 32 ± 4% (range 10 to 51%). All patients with coronary artery disease had previous myocardial infarction and 2 patients had LV aneurysm. In 11 patients, an automatic internal cardioverter-defibrillator (AICD, Intec Systems) had been placed. Treatment with 5 ± 0.4 previous drugs (range 3 to 8) had failed, defined as symptomatic arrhythmia recurrence, continued spontaneous VT on 24-hour Holter monitoring, VT induction by PES, or intolerable side effects from drugs. In all but 1 patient, treatment with at least 1 previous experimental antiarrhythmic agent (mean 1.6 drugs) had failed.

Electrophysiologic study: Control electrophysiologic study was performed after treatment with all antiarrhythmic agents (other than digoxin and β-blocking drugs) had been discontinued for 48 hours. Late PES (at least 6 weeks after amiodarone therapy started) was performed in all patients. All patients who received digoxin or β-blocking drugs during the control study continued to receive them to the time of late study.

Each patient gave informed consent for the study. Electrophysiologic studies were performed with the patient in the postabsorptive, nonsedated state. Standard quadripolar electrode catheters (10-mm interelectrode distance) were inserted through the femoral, brachial or subclavian veins; the right femoral artery was cannulated for hemodynamic monitoring and for LV stimulation if necessary. Programmed ventricular stimulation was performed using a digital stimulator that delivers rectangular pulses 1 ms in duration at twice diastolic threshold (less than 4 mA). Surface leads 1, avF, V_1, V_5 and intracardiac electrograms were simultaneously displayed on an oscillographic recorder (Electronics for Medicine VR-16). Analog data were displayed on a spray-ink recorder (Mingograf) for real-time analysis at paper speeds of 25, 50 and 100 mm/s and stored on magnetic tape for retrieval. Programmed ventricular stimulation was performed using single (S_1S_2) and double ($S_1S_2S_3$) extrastimuli at 3 basic ventricular pacing cycles (S_1S_1) (600, 500, 450 ms), followed by rapid ventricular decremental burst pacing (V_{burst}:10 consecutive beats at decreasing cycle lengths until 2:1 pacing noncapture). PES was performed in at least 2 right ventricular (RV) sites (apex and outflow tract) and 2 LV sites (apex, septum or anterolateral wall) if sustained VT was not induced. Refractory periods were measured at the same paced cycle length and site of stimulation before and after therapy for purpose of comparison.

TABLE II Results of Control and Late Programmed Electrical Stimulation in Patients Receiving Amiodarone Treatment

Control PES		Late PES	
10	Sustained VT	10	Sustained VT
1	Sustained VT	1	Noninducible
1	Nonsustained VT	1	Sustained VT
1	Nonsustained VT	1	Nonsustained VT

PES = programmed electrical stimulation; VT = ventricular tachycardia.

Definitions: *Nonsustained VT* was defined as VT that was reproducible (2 of 3 attempts) ≥ 3 repetitive ventricular beats that terminated spontaneously within 30 seconds and *sustained* VT as VT that lasted at least 30 seconds or required termination by ventricular overdrive pacing or external cardioversion due to hemodynamic compromise or degeneration into ventricular fibrillation. *Noninducibility* was defined as inability to induce VT at 2 RV and 2 LV sites using the protocol outlined above, and *ease of inducibility* was assessed by comparing the mode of extrastimulation and number of sites tested in control vs late PES testing. Easier induction required fewer extrastimuli (i.e., S_1S_2 vs $S_1S_2S_3$ vs V_{burst}) or fewer sites tested (i.e., RV apex vs RV apex + RV outflow tract, or RV site vs LV site) to induce VT.

Amiodarone administration: Physical examination, 12-lead electrocardiography, 24-hour Holter monitoring, complete blood count, basic chemistry screen including liver function tests, thyroid function tests, and ophthalmologic evaluation with slit-lamp examination were performed. All patients gave informed consent before amiodarone administration.

Twenty-four-hour Holter monitoring (Avionics model 445B) was performed using dual-channel recordings. The magnetic tapes were analyzed using a Del Mar Avionics model 660 Dynamic Electrocardio Scanner®. All tapes were reviewed by at least 2 of the investigators and VT was defined as at least 3 repetitive ventricular beats at a rate of more than 100 beats/min. The oral loading dose was 1,200 mg/day for 14 days and the maintenance dose ranged from 200 to 800 mg/day (mean 408 ± 20). In no patient was another antiarrhythmic agent added after control PES study.

Follow-up: Patients were followed in the Sudden Death Prevention Clinic at 2, 3, 4, 6, 9 and 12 months after discharge and every 6 months thereafter. Interim recurrent clinical arrhythmic events (syncope, sudden death or AICD discharge) and any adverse side effects were recorded. In cases of AICD discharge, the first discharge was considered a sudden death event for that patient. Physical examination, 12-lead ECG, 24-hour Holter, and repeat baseline blood studies were obtained at each visit. In addition, an external analyzer (AID CHECK, Intec Systems) was used to determine the number of AICD discharges delivered.

Amiodarone efficacy: We defined efficacy of amiodarone based on the absence of clinical arrhythmic events after starting amiodarone. Amiodarone was considered to be effective if the patient remained free of clinical arrhythmic event through follow-up.

Statistical analysis: The data are presented as mean ± standard error. Data were tested for significance by paired and unpaired Student t tests; a p value <0.05 was accepted as the limit of significance.

TABLE III Control and Late Electrophysiologic Variables in Seven Patients Treated with Amiodarone Alone

	Control	Late	p Value
RR	785 ± 50	895 ± 44	p <0.025
PR	173 ± 8	198 ± 11	p <0.005
QRS	99 ± 11	114 ± 13	p <0.05
QTc	441 ± 14	471 ± 20	NS
AH	100 ± 4	107 ± 8	NS
HV	57 ± 8	65 ± 5	NS
RV-ERP	250 ± 11	277 ± 14	p <0.025

All values are in milliseconds.
NS = not significant; RV-ERP = right ventricular effective refractory period.

Results

Control electrophysiologic study: At control electrophysiologic study, VT was induced in all patients: sustained VT in 11 and nonsustained VT in 2 (9 beats and 31 beats). The morphologic characteristics of the VT (bundle branch pattern and axis) were identical in all instances to the spontaneous clinical VT noted on 12-lead electrocardiogram or dual-channel Holter monitor. The induced VT cycle length ranged from 165 to 405 ms (mean 268 ± 16). Ten patients had VT induced on the right side (S_1S_2: 4; $S_1S_2S_3$: 4; V_{burst}: 2); in 3 patients VT was induced from the left ventricle (all using $S_1S_2S_3$ mode).

Late electrophysiologic study: Late PES testing was performed in all patients at 6 ± 1.6 months (range 6 weeks to 15 months) after starting amiodarone. VT was induced in 12 patients: sustained VT in 11 and nonsustained (32 beats) in 1 patient. Again, in all instances the morphologic characteristics of the VT were identical to the spontaneous clinical VT. The induced VT cycle length ranged from 202 to 465 ms (mean 324 ± 21). Ten patients had VT induced on the right side (S_1S_2: 2; $S_1S_2S_3$: 6; V_{burst}: 2) and 2 patients required left ventricular stimulation to induce VT (both using $S_1S_2S_3$ mode).

Table II is a summary of the results at both control and late PES. Of the 11 patients with inducible sustained VT at control study, only 1 patient had VT suppressed at late PES. One patient with inducible nonsustained VT (31 beats) at control study had sustained VT induced at late study. The other patient with inducible nonsustained VT (9 beats) at control study had nonsustained VT (32 beats) induced at late study.

The VT cycle length at late study compared to control study was significantly increased (324 ± 21 vs 268 ± 16 ms, p <0.005). The VT cycle length was increased in 10 patients, decreased in 1 and unchanged in 1. The mean VT cycle length change was +70 ms (range −88 to 140 ms). Based on our criteria for ease of inducibility, inducibility was unchanged in 4, easier in 4 and more difficult in 4.

The hemodynamic response (systolic blood pressure) to induced VT was significantly improved at late study compared to control study (61 ± 12 vs 48 ± 12 mm Hg, p < 0.05).

Chronic electrophysiologic effects: There were 7 patients treated with amiodarone alone (no digoxin or β-blocking drugs) in whom intracardiac conduction times and RV effective refractory periods (ERP) at control and late study could be compared. Table III is a summary of the findings. Amiodarone significantly increased sinus cycle length (RR), PR interval, QRS duration and RVERP.

TABLE IV Comparison of Patients With and Without Clinical Arrhythmic Events

	Nonevent	Event	p Value
No. of pts	8	5	
Ejection fraction	30 ± 5	36 ± 5	NS
Inducible VT (late PES)	8	4	
VT cycle length (late PES)	333 ± 20	311 ± 52	NS
VT cycle length change	65 ± 16	85 ± 22	NS
Systolic BP response to VT (control PES)	50 ± 16	43 ± 19	NS
Systolic BP response to VT (late PES)	65 ± 15	53 ±11	NS
Change in RVERP	24 ± 5	20 ± 3	NS
Ease of VT inducibility			
Unchanged	3	1	
Easier	2	2	
More difficult	3	1	

BP = blood pressure; NS = not significant; PES = programmed electrical stimulation; RVERP = right ventricular refractory period; VT = ventricular tachycardia.

Holter monitoring: All patients had documented spontaneous nonsustained VT when not receiving antiarrhythmic agents (other than digoxin and β-blocking drugs) on the baseline 24-hour Holter recording. Patients had 9.7 ± 1.2 twenty-four-hour Holter recordings after 1 week of therapy through follow-up. Spontaneous nonsustained VT was completely suppressed in 7 patients (54%). Three patients without subsequent clinical arrhythmic events had nonsustained VT on any follow-up Holter (4 of 30 total Holter recordings). Three patients with subsequent events had nonsustained VT on any follow-up Holter (8 of 34 total Holter recordings). In each instance, nonsustained VT was 3 to 10 beats and asymptomatic.

Clinical efficacy: At 24 ± 2 months of follow-up (range 4 to 38), 8 patients (62%) were free of clinical arrhythmic events. All of these patients had inducible sustained VT at both control and late PES. Of the 5 patients (38%) with clinical arrhythmic events, 4 had inducible VT (3 sustained VT, 1 nonsustained VT) at late study. Clinical arrhythmic events manifested as recurrent sudden death in 4 patients (3 had AICD discharges with successful cardioversion-defibrillation) and syncope in 1 patient. Of the 11 patients with inducible sustained VT at late study, only 3 patients (27%) had clinical arrhythmic events.

Table IV is a summary of the findings in patients with and without clinical arrhythmic events. There were no significant differences in VT cycle length, VT cycle length change, ease of VT inducibility, or hemodynamic response to induced VT at late PES in patients with or without arrhythmic events. Likewise, there were no significant differences in these variables in a subset analysis that excluded patients with inducible nonsustained VT at either control or late PES.

Nine patients (69%) were alive at follow-up. Four patients died: 2 suddenly and 2 from refractory heart failure. The mean EF in the surviving patients was significantly better than that in patients who died, 37

TABLE V Comparison of Programmed Electrical Stimulation Studies in Patients Receiving Amiodarone Treatment

	No. of Pts	PES	Inducible	Follow-Up	Events*
Heger et al[12]	19	2–4 wk	18 (95%)	12.7 mo	6 (33%)

Present study	13	1.5–15 mo	12 (92%)	24 mo	4 (33%)

* Number and percent of patients in whom VT could be induced with clinical arrhythmic events.
† Represents patients with clinical arrhythmic events of total population.
‡ Represents only patients who had VT as easily or more easily induced compared to control study.
§ Includes 5 patients who had clinical VT recurrence and 1 patient who had morphologically new arrhythmia induced.
PES = programmed electrical stimulation; VT = ventricular tachycardia.

± 3% vs 19.5 ± 5% ($p < 0.01$). A significant difference remained if the 3 patients with resuscitated sudden deaths were included as patients dead at follow-up.

Side effects: Significant side effects were noted in 4 patients (31%); 1 patient (8%) required drug withdrawal. Two patients had asymptomatic elevated liver function tests manifested by 2 to 3-fold elevations in transaminases and concomitant elevated thyroid function tests; 1 patient underwent permanent pacemaker insertion due to symptomatic sinus bradycardia. In 1 patient, a progressive sensory-motor neuropathy developed.

Discussion

Role of programmed electrical stimulation: The ability of certain antiarrhythmic agents to prevent the induction of VT in patients with recurrent VT is predictive of the drug efficacy in eliminating spontaneous recurrences during short-term and long-term therapy.[28–30] Conversely, induction of sustained ventricular tachyarrhythmias during conventional type I antiarrhythmic drug therapy by PES predicts recurrence of clinical arrhythmia. In the case of amiodarone, most studies have revealed a disparity between electrophysiologic and clinical efficacy,[12–15,18–21] whereas others have suggested a predictive role of PES.[22–24]

Our study supports the discrepancy in clinical and electrophysiologic efficacy of amiodarone. In this series, electrophysiologic study was performed more than 6 weeks (mean 6 months) after starting amiodarone, which is 3 to 6 times longer than previous studies and well into the projected steady-state period.

Table V is a summary of the results of previous studies in comparison to the present study. Twelve of 13 patients (92%) had inducible VT at late PES testing. This is similar to the findings of Heger et al,[12] Hamer et al,[18] and Waxman,[20] but is somewhat higher than that reported by others.[14,15,19,21–24]

At 24 ± 2 months of follow-up only 4 of 12 patients (33%) with inducible VT at late PES had had recurrent clinical arrhythmic events. This is similar to the 33% and 27% reported by Heger et al[12] and Haffajee et al,[15] respectively. In our series, only 3 of 11 patients with inducible sustained VT at late PES had clinical arrhythmic events. Similarly, only 2 of 10 patients with inducible sustained VT at both control and late PES studies had events. The only converter from inducible VT to noninducible in our series had recurrent spontaneous VT with syncope at 15 months of therapy.

Although we have reported AICD discharges during supraventricular tachyarrhythmias,[31] none of the patients with AICD discharges in the present study had histories of supraventricular tachyarrhythmias and the premonitory symptoms before AICD discharge were always similar to previous episodes of VT. Thus, we feel that AICD discharge was justified as an endpoint event.

McGovern and Ruskin,[22] using a grading system similar to ours to determine the ease of VT inducibility, reported that long-term clinical outcome was predicted by the PES results in 77% of patients. In the present study, the ease of VT induction was variable in patients with and without events and, thus, was not predictive. This is in agreement with the findings of Waxman et al,[13] who demonstrated the failure of amiodarone to alter the ease of VT induction in any consistent fashion at shorter follow-up study time.

Amiodarone lengthens the action potential duration, prolongs refractoriness and slows impulse conduction in ventricular myocardium.[3] As noted in earlier studies, the VT cycle length in most patients was prolonged. Similarly, the RVERP was lengthened by 11%, which is within the 8 to 23% range noted previously.[12–14,18,19,22,24,27,32] However, there were no significant differences in VT cycle length, VT cycle length change, or RVERP change comparing patients with and without clinical arrhythmic events at follow-up. Therefore, amiodarone clearly has effects on electrophysiologic characteristics of ventricular tissue and on the induced VT rate, but these effects do not appear to correlate with clinical outcome. This leads to the speculation that most patients still have the vulnerability for sustained VT, but that the protective mechanism may lie in suppression of ventricular ectopic activity or abolition of triggers that initiate clinically important ventricular arrhythmias.

Although nonclinical morphologic forms of ventricular tachyarrhythmias in addition to the clinical spontaneous forms can be induced by PES,[33] in our series only clinical VT morphologic patterns were induced. This is in contrast to the findings of Saksena et al,[24] who reported that in 42% of patients receiving chronic amiodarone therapy, morphologically new ventricular tachyarrhythmias were induced by PES. These investigators used a much more aggressive stimulation protocol.

Differences in patient populations, amiodarone loading and maintenance dosage, interval between control and follow-up electrophysiologic study, programmed stimulation protocols, and definitions of induced VT may account for the discrepancies between our PES findings and those of previous studies.

Clinical efficacy: At 24 ± 2 month follow-up, 62% of the patients were free of clinical arrhythmic events. This degree of efficacy concurs with that of most previous studies,[6,9,10–13,16] but is somewhat less than that reported by others.[5,7,8,14,15] Again, discrepancies in efficacy can be accounted by differences in patient populations, drug dosage, duration of therapy, and definitions of efficacy. Our patients had a mean 3.5 episodes of sustained VT in the year preceding referral and 92% had failed at least 1 previous experimental agent (mean 1.6). Thus, the efficacy rate of 62% may reflect the response in a group of patients at exceptionally high risk.

Although overall LV function (EF) did not predict clinical arrhythmic events, the mean EF certainly was worse in patients who later died from a cardiac cause. This concurs with the findings of Swerdlow et al,[34] who reported overall LV function as an important determinant of survival from cardiac death in patients with ventricular tachyarrhythmias.

Side effects: In our series, significant side effects were noted in 31% of patients, yet only 8% required drug withdrawal. These findings are consistent with most previous studies.[5–8,10–12,14,15]

Conclusions: We conclude that although amiodarone is an effective, fairly well-tolerated antiarrhythmic agent in patients with refractory, recurrent VT, late PES testing does not predict clinical efficacy. Indeed, the frequency of conversion from inducible VT to noninducible VT is low. Further insight into the protective action of amiodarone may be achieved by efforts aimed at understanding the triggering mechanisms for onset of spontaneous ventricular tachyarrhythmias.

Acknowledgment: We express our gratitude to Sandra Waclawski, RN, Sarah Ord, BS, Katherine Critikos and Jenny Beeker for technical support, to Toni Haase for secretarial assistance, and to Myron L. Weisfeldt, MD, for his thoughtful critique of the manuscript.

Comparison in the Same Patient of Two Programmed Ventricular Stimulation Protocols to Induce Ventricular Tachycardia

PEDRO BRUGADA, MD, and HEIN J. J. WELLENS, MD

In 24 consecutive patients with documented ventricular tachycardia (VT) (22 patients) or fibrillation (VF) (2 patients), results of 2 programmed ventricular stimulation protocols to initiate VT/VF were prospectively studied. Seventeen patients had VT/VF after a healed myocardial infarction (MI) and 7 patients had idiopathic VT. In both protocols (designated 1 and 2), the right ventricular (RV) apex was paced at 100 beats/min, using a maximum of 2 ventricular premature complexes (VPCs) given at twice diastolic threshold. This protocol had a sensitivity of 25%. In protocol 1, the pacing site was changed to the RV outflow tract and the previous steps were repeated; in protocol 2, the pacing rate was increased to 120 and 140 beats/min at the RV apex, also using a maximum of 2 VPCs. The next step in protocol 1 consisted of increase of current strength to 20 mA and repeating previous steps at the RV apex and RV outflow tract, with a maximum of 2 VPCs; in the next step in protocol 2, three VPCs were used during sinus rhythm and pacing was performed at rates of 100, 120 and 140 beats/min. In protocol 1, therefore, only stimulation site and current strength were changed, while in protocol 2 only pacing rate and number of VPCs were modified. Protocol 1 had a sensitivity of 54% and protocol 2 a sensitivity of 83%. The sensitivity of protocol 2 was statistically higher than that of protocol 1 ($p < 0.05$). In the group of patients with VT after MI, the sensitivity was 66% for protocol 1 and 93% for protocol 2. Protocol 2 combined with administration of isoproterenol had a sensitivity of 95% (100% in the patients with VT after MI).

These observations have important implications for the design of the most successful order of programmed ventricular stimulation in patients with documented VT/VF. If stimulation at the RV apex using a single pacing rate and 2 VPCs given at twice threshold fail to initiate VT, increase of pacing rate and, thereafter, use of 3 VPCs is a much more effective means of initiating VT than changing the stimulation site to RV outflow tract or increasing the current strength to 20 mA.

(Am J Cardiol 1985;55:380–383)

Programmed electrical stimulation of the heart was introduced in clinical cardiology in 1967.[1,2] Since then, the technique has gained wide acceptance for studying patients with supraventricular or ventricular arrhythmias. The initial studies showed that some tachycardias could be easily reproduced by this technique; other tachycardias could not be induced or only rarely induced.[3–7]

With the introduction of programmed stimulation in clinical cardiology, an ever-growing variety of stimulation protocols became available. This is troublesome when trying to understand results of programmed stimulation in patients with documented ventricular tachycardia (VT) or fibrillation (VF) or when trying to identify patients at risk of arrhythmic complications.[8–10] In patients with electrocardiographically well documented VT or VF, programmed stimulation is used to understand modes of initiation and termination of the arrhythmia, its site or origin and pathways, possible mechanisms, and to study the effect of antiarrhythmic therapy on the tachycardia mechanisms. Programmed stimulation should reproduce the arrhythmia rapidly and effectively. To determine the sensitivity of different ventricular stimulation protocols, a prospective study was undertaken comparing 2 different protocols in the same patient.

Methods

Twenty-four consecutive patients were studied by programmed ventricular stimulation. All gave informed consent

TABLE I Pacing Modalities Used in Protocol 1 and Protocol 2

Steps	Protocol 1	Protocol 2
First	Common	Common
Second	Change pacing site	Increase pacing rate
Third	Increase current strength	Increase number VPCs

VPC = ventricular premature complex.

TABLE II Mode of Initiation of Ventricular Tachycardia/Fibrillation in 24 Patients

Mode of Initiation	VT/VF-MI	VT Idiopathic
Ventricular stimulation alone	16/17	4/7
Isoproterenol alone	0/1	2/3
Isoproterenol and ventricular stimulation	1/1	0/1
VT not initiated	0/17	1/7

VT = ventricular tachycardia; VT/VF-MI = ventricular tachycardia/fibrillation after myocardial infarction.

and none was receiving antiarrhythmic drug treatment. Twenty-two patients had documented sustained VT and 2 patients documented VF. VT or VF occurred without relation to a new ischemic event in these patients. Seventeen patients had a healed MI (VT-MI) and 7 patients had idiopathic VT.

Methods of stimulation, recording and analysis of tracings have been described.[3] Electrode catheters were placed at the right atrium, right ventricular (RV) apex, RV outflow tract and His bundle area. To compare results of the 2 protocols, VT or VF was initiated at least twice in each patient. The study was terminated immediately, however, when the patient required 2 direct-current countershocks to terminate VT or VF resulting in loss of consciousness.

Two protocols were used on each patient.

Protocol 1: Protocol 1 consisted of 8 steps: (1) 1 ventricular premature complex (VPC) given at the RV apex during pacing at a rate of 100 beats/min at twice threshold; (2) 2 VPCs given at the RV apex during pacing at 100/beats/min at twice threshold; (3) 1 VPC given at the RV outflow tract during pacing at 100 beats/min at twice threshold; (4) 2 VPCs given at the RV outflow tract during pacing at 100 beats/min at twice threshold; (5) 1 VPC given at the RV apex during pacing at 100 beats/min using 20 mA; (6) 2 VPCs given at the RV apex during pacing at 100 beats/min using 20 mA; (7) 1 VPC given at the RV outflow tract during pacing at 100 beats/min using 20 mA; and (8) 2 VPCs given at the RV outflow tract during pacing at 100 beats/min using 20 mA.

Protocol 2: Protocol 2 consisted of 12 steps: (1) 1 VPC given at the RV apex during sinus rhythm at twice threshold; (2) 2 VPCs given at the RV apex during sinus rhythm at twice threshold; (3) 1 VPC given at the RV apex during pacing at 100 beats/min at twice threshold; (4) 2 VPCs given at the RV apex during pacing at 100 beats/min at twice threshold; (5) 1 VPC given at the RV apex during pacing at 120 beats/min at twice threshold; (6) 2 VPCs given at the RV apex during pacing at 120 beats/min at twice threshold; (7) 1 VPC given at the RV apex during pacing at 140 beats/min at twice threshold; (8) 2 VPCs given at the RV apex during pacing at 140 beats/min at twice threshold; (9) 3 VPCs given during sinus rhythm at the RV apex at twice threshold; (10) 3 VPCs given at the RV apex during pacing at 100 beats/min at twice threshold; (11) 3 VPCs given at the RV apex during pacing at 120 beats/min at twice threshold; and (12) 3 VPCs given at the RV apex during pacing at 140 beats/min at twice threshold.

All stimuli were bipolar and had a duration of 2 ms both in protocols. Diastolic thresholds were less than 1.5 mA. In only 1 patient was VT initiated by giving 1 and 2 VPCs during sinus rhythm. In that patient, VT was also initiated by giving 1 VPC during pacing at the RV apex at a rate of 100 beats/min. This allowed us to compare the results of protocol 1 and protocol 2 after an initial common step, which consisted of pacing at the RV apex at 100 beats/min using a current strength of twice threshold and up to 2 VPCs. After this common step, pacing site was changed to the RV outflow tract in protocol 1, whereas stimulation was continued from the RV apex and the pacing rate was increased in protocol 2. The next step in protocol 1 was an increase of current strength to 20 mA, whereas the number of VPCs was increased in protocol 2. These steps are summarized in Table I. When stimulation was completed and if VT had not been initiated, isoproterenol was given intravenously to produce an acceleration in sinus rate of 20%. If isoproterenol alone did not induce VT, stimulation was repeated under isoproterenol using the same sequence as previously described. Results obtained during administration of isoproterenol, however, were not included to evaluate results of protocol 1 or protocol 2. Using our simultaneous recording of many electrocardiographic leads, only ventricular arrhythmias similar to those clinically documented were used for evaluation of results. Nonsustained VT was not considered the clinical ventricular arrhythmia in any of these patients, who all suffered from sustained ventricular arrhythmias (lasting longer than 30 seconds or producing loss of consciousness). Other definitions to classify the different types of ventricular arrhythmias used in our laboratory have been described.[11,12] Statistical analysis was performed using the chi-square test.

Results

Table II is a summary of the mode of initiation of VT in the 24 patients, in relation to the cause of VT. The clinical ventricular arrhythmia was initiated by ventricular stimulation in all but 1 patient in the VT-MI group. In that patient, VT was initiated by stimulating during intravenous administration of isoproterenol. VT was initiated by ventricular stimulation in 4 of 7 patients in the idiopathic-VT group. In 2 of the 3 other patients in this group, VT was initiated by isoproterenol without need for electrical stimulation. In the remaining patient, VT could not be induced. Twenty-two patients underwent a complete stimulation study using protocol 1 and 23 patients underwent a complete stimulation study using protocol 2. The reasons for not completing the protocols were repeat cardioversions in 1 patient and chest pain during 20-mA stimulation in the other 2.

Figure 1 illustrates the sensitivity of protocols 1 and 2 in patients in the VT-MI group. The earliest step in the program that resulted in initiation of sustained VT was considered for analysis of sensitivity. Protocol 1 had a sensitivity of 66% and protocol 2 a sensitivity of 93%. When sensitivity of these protocols were compared only for the VT-MI group, results were not statistically significant ($\chi^2 = 3.6382$, $0.05 < p < 0.1$). When the whole population of patients was considered, however, protocol 2 had a sensitivity of 83%, which was significantly higher than that of protocol 1 (54%) ($p < 0.05$).

Figure 1 illustrates another important point. Stimulation was more extensive during protocol 2 than protocol 1. Therefore, it was important to know whether, protocol 2, included more ineffective steps

than protocol 1. There were 120 possible steps for the 15 patients of the VT-MI group in protocol 1, compared with 180 possible steps for the 16 patients of the same group when using protocol 2. In protocol 1, 74 steps were ineffective to initiate VT (relative inefficacy 0.62), and in protocol 2, 97 steps were ineffective (relative inefficacy 0.56, a value of 1.0 indicating a completely ineffective program). These results shows that protocol 2 markedly increased sensitivity to initiate VT, without increasing the relative number of ineffective stimulation steps, compared to protocol 1.

Results of protocol 1 and protocol 2 can also be illustrated, as in Figure 2, by considering changes in pacing modality that each program contained. A pacing protocol using up to 2 VPCs given at twice threshold during pacing at the RV apex at 100 beats/min was taken as initial common step for both protocols. This step had a sensitivity of 25%. A change in pacing site to the RV outflow tract in protocol 1 increased sensitivity to 33%, and an increase of current strength to 20 mA increased sensitivity to 66%. Using the steps of protocol 2 however, by simply increasing the pacing rate, sensitivity increased to 68%, which was higher than the sensitivity reached by the entire protocol 1. Thereafter, by using 3 VPCs during sinus rhythm and ventricular pacing, a sensitivity of 81 and 93% was reached with protocol 2.

Isoproterenol: Results of administration of isoproterenol were not considered for evaluation of sensitivity of either protocol because patients in whom VT was not induced by protocol 1 but in whom it was induced by protocol 2 did not receive isoproterenol. When results with isoproterenol were added to results of protocol 2, however, sensitivity increased to 95% for the whole patient population and to 100% in the VT-MI group.

Discussion

When using programmed ventricular stimulation in patients with well documented VT or VF, the most important aspect of the protocol is its sensitivity in reproducing VT, rather than specificity. Electrical stimulation should reproduce VT rapidly and effectively. Specificity of electrical stimulation becomes of major importance, however, when patients with no documented VT undergo programmed ventricular stimulation either to clarify symptoms suggesting arrhythmias or to identify patients at high risk of arrhythmic complications. We have extensively discussed elsewhere that specificity of electrical stimulation can be markedly improved when not only the mode of initiation of VT is considered but also the type of arrhythmia initiated is carefully analyzed.[11,12]

In this study 2 protocols were compared in the same patient. We preferred this approach to a randomized study because we did require initiation of VT in all patients with documented VT. When patients would have been randomized, we had the risk of not inducing VT in a significant percentage of patients randomized to 1 of the 2 protocols. When VT would have not been induced we would have been unable to proceed further in the evaluation of these patients by programmed stimulation. Therefore, we used both protocols in all patients, and let the patient serve as his own control. The

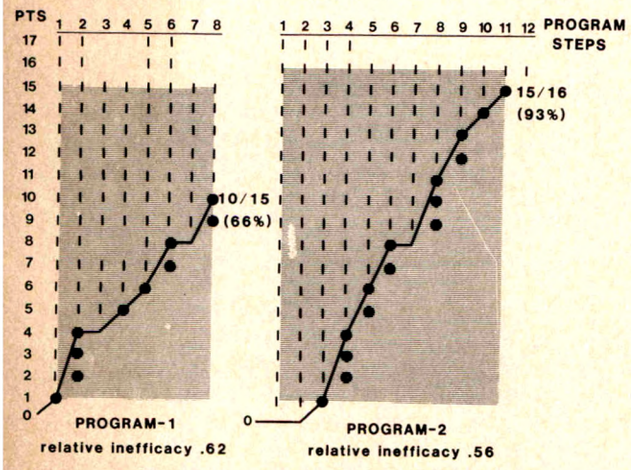

FIGURE 1. Sensitivity of protocols 1 and 2 in the patients with ventricular tachycardia/fibrillation after myocardial infarction. The steps of each protocol are shown at the **top** (8 steps for protocol 1 and 12 steps for protocol 2. Each **vertical line** indicates a particular stimulation step. Two patients did not complete protocol 1 and 1 patient did not complete protocol 2. The **dots** indicate the earliest step during each protocol resulting in initiation of sustained ventricular tachycardia. The **dashed area** represents the total possible stimulation steps in each protocol, and indicates that protocol 2 was more extensive than protocol 1. The relative inefficacy of the 2 protocols was, however, similar (0.62 and 0.56). Protocol 1 reached a sensitivity of 66% and protocol 2 a sensitivity of 93%.

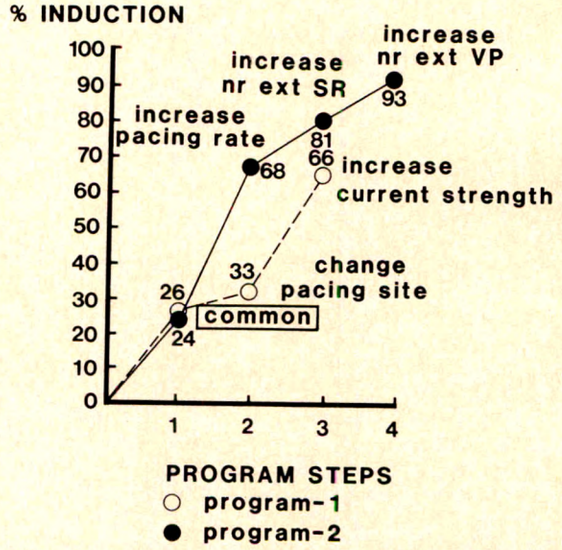

FIGURE 2. Sensitivity of protocols 1 and 2 in the group of patients with ventricular tachycardia/fibrillation after myocardial infarction by considering the different pacing modalities used during each protocol. After a common step that used a single pacing rate and 2 ventricular premature complexes (VPCs) given at twice threshold at the right ventricular apex (sensitivity 25%), increase in pacing rate and use of 3 VPCs was more effective in initiating VT than change in pacing site or increase of current strength to 20 mA. Nr ext = number of VPCs; SR = sinus rhythm; VP = ventricular pacing.

results showed that protocol 2 had a much higher sensitivity than protocol 1 in reproducing VT.

Relevance for the design of standard ventricular stimulation protocols: A standardized protocol used order by all groups performing electrical stimulation studies would facilitate understanding of results of programmed stimulation in different patient populations. Richards et al[13] reported a protocol identical to protocol 1 of our study. They reported a sensitivity of 89% in a series of 27 patients with documented VT/VF. In the 24 patients that we studied prospectively, this high sensitivity could not be confirmed. There are several reasons for this, including the definitions used to classify a study as positive. Richards et al used a cutoff point of 10 seconds to consider a ventricular arrhythmia as sustained, and they did not classify the types of ventricular arrhythmias initiated. In our study only ventricular arrhythmias such as those suffered clinically by the patient, and lasting at least 30 seconds, were considered as a positive result. Richards et al[9] also reported a specificity of 100% for the same protocol to identify patients after MI prone to develop VT or sudden death. While the positive predictive value of their protocol was extremely low (26%), the value of programmed electrical stimulation to identify candidates to arrhythmic complications after MI has not been confirmed.[10] Sensitivity of programmed stimulation in patients with documented sustained VT or VF using a pacing protocol similar to our protocol 2 has been greater than 80% in other laboratories.[14–17] This sensitivity was confirmed in the present study.

Morady et al[18] reported a study of programmed ventricular stimulation. They compared triple stimuli to left ventricular stimulation in 2 groups of patients. Although the patients were not randomized, the clinical data of the 2 groups were similar. Morady et al concluded that the initial use of burst overdrive pacing and single and double extrastimuli in the right ventricle can obviate need for triple extrastimuli in 53% of patients. However, one must realize that this pacing protocol also included stimulation in the RV outflow tract or RV septum in addition to stimulation at the RV apex. Morady et al also concluded that triple extrastimuli were required in 24% of patients. They did not report results regarding the relative inefficacy of their protocols A and B. This is important because the sensitivity of our protocol 2 was similar to that of their protocol. Their protocol had 33 steps. How many of these steps were undertaken and were ineffective to reproduce VT remains unknown from the data they reported.

The difficulties of our prospective study comparing 2 protocols in the *same* patient should not be underestimated. Initiation of VT at least twice was necessary in each patient, including those who required external direct-current countershock to terminate VT. Despite the small size of our study group, the differences between protocol 1 and protocol 2 were statistically significant, and the study was terminated.

In conclusion, we suggest that when a stimulation protocol using up to 2 VPCs from the RV apex at twice threshold during pacing at 100 beats/min fails to initiate VT, increase of the pacing rate using 3 VPCs during sinus rhythm and ventricular pacing is a more effective means of initiating VT than change of pacing site to RV outflow tract or increase of current strength to 20 mA. Administration of isoproterenol and stimulation during isoproterenol can further increase sensitivity of programmed stimulation.

Late Potentials in Normal Subjects and in Patients with Ventricular Tachycardia Unrelated to Myocardial Infarction

HUMBERTO COTO, MD, CLAUDIO MALDONADO, MA, PRASAD PALAKURTHY, MD, and NANCY C. FLOWERS, MD

Fifty normal male and female athletes, or athletically active subjects, were evaluated, and a search for low-amplitude late potentials in the terminal part of ventricular activation was performed. Recordings from 3 normal men met the definition of abnormal late potentials, and were indistinguishable by present analytic techniques from those encountered in patients who have ventricular tachycardia (VT) after myocardial infarction (MI). Of 24 patients studied, 11 had VT, but only 2 had had an MI, which occurred in the remote past. Another patient had 1 narrowed coronary artery on arteriography. Group differences could be demonstrated using amplitudes and durations of late potentials, but late potentials generally did not prove the impressive marker of the patient with VT, which other workers, as well as ourselves, have encountered in patients after MI. Late potentials were an impressive marker in a subset of the VT group in whom cardiomegaly developed. Thus, the absence of late potentials is an effective marker in the normal subject, but the presence of late potentials is not an effective marker in identifying the patient with non-MI-related, nonsustained VT before development of cardiomegaly.

(Am J Cardiol 1985;55:384–390)

In 1973, Boineau and Cox[1] demonstrated slow ventricular activation, in association with a recent myocardial infarction (MI), as a source of reentrant premature ventricular depolarizations. Berbari et al[2] reported arrhythmogenic ventricular activity occurring during the ST segment in 1978. In the early 1980s, Simson,[3] Breithardt et al[4] and, more recently, other investigators, evaluated late potentials as a possible means of identifying certain patients prone to ventricular tachycardia (VT). Late potentials may be thought of as deflections occurring after the dominant QRS-wave form that are relatively high in frequency and too low in amplitude to be distinguishable from noise without the application of additional noise reduction and signal enhancing techniques such as amplification, filtering and signal averaging. Based on either the duration of relatively low amplitude deflections in the terminal QRS or the ST segment, or the determination of the root-mean-square (RMS) of the voltage over a particular time period after the basic QRS wave form, certain group and possibly individual differences may be shown between those patients who sustained MI and later had VT and those who did not. One difficulty in extending these initial nosologic observations further is the scarcity of information on the incidence of low-amplitude late potentials in normal subjects.[5] Our study characterizes the occurrence of late potentials in a normal and athletically active group who had not sought entry into a health care system, and evaluates the predictive accuracy of late potentials in distinguishing another population subset with VT from causes other than MI.

Methods

Fifty normal subjects, all of whom either were athletes (n = 38) or exercised regularly (n = 12), were studied. Before inclusion into the study, each subject had a cardiovascular history taken and underwent physical evaluation, including a detailed smoking and family history. None were included who had a family history of early heart disease or who smoked in excess of 10 cigarettes daily. All subjects had a normal routine electrocardiogram (ECG). The ages of the 26 men and 24 women ranged from 18 to 36 years (mean 25.0 ± 5.8).

An additional 24 patients, recently referred for problems relating to cardiac rhythm or conduction, were considered for the study. One patient had right bundle branch block with a standard QRS duration of 130 ms. Another patient had an intraventricular conduction defect with a QRS of 140 ms. All other patients had standard QRS durations less than 120 ms. Eleven with nonsustained VT will be considered in this report. Each was symptomatic, had repetitive episodes, and therapy was required for control. All of the 11 had episodes that

stopped within 30 seconds, and all had demonstrated at least a 5-beat salvo. One patient had an occasional episode (by definition a sustained VT), lasting longer than 30 seconds. No patient had acute MI and only 2 had remote MI. Another patient had an occlusion larger than 75%, visualized in 1 coronary artery and 1 had insignificant plaque formation. The remaining causes were specifically not coronary artery disease and included mitral valve prolapse, idiopathic dilated cardiomyopathy, overdosage of Mellaril® in 1 patient, essential hypertension and aortic valve disease.

The recording and signal-averaging process was performed with a system from Arrhythmia Research Technology which uses essentially the instrumentation described by, and the software developed by, Simson et al.[3,6] In many instances, normal subjects and patients were recorded on more than 1 occasion to verify stability. In brief, 3 relatively orthogonal sampling points were amplified at a gain of 1,000, with a band width of 0.05 to 300 Hz, with a noise level of 0.7 μV referred to input. The signal from each lead was further amplified 5 times and passed through a 4-pole, 250-Hz low-pass filter. Analog-to-digital conversion was performed to 12-bit accuracy at a sampling rate of 1,000/s on a Hewlett-Packard 9826 computer, and the information was stored on floppy disks. Each lead was recorded for $2\frac{1}{2}$ minutes. With the Z lead as temporal reference lead, an 8-point template began at a reference time and extended for 128 ms to include distal QRS and early ST segment. The initial 8-beat template was accepted if the mean standard deviation after direct current shift was under 20 μV. Subsequent beats were tested against the template and accepted when within twice template standard deviation. During averaging, a 512-ms segment of the heart beat was identified, beginning 100 ms before onset of the QRS, and the template updated every fourth beat. After averaging, the records were filtered to eliminate low frequencies using a high-pass filter (HPF) at both 25 and 50 Hz in the present protocol. A bidirectional digital filter modified by Simson et al[6] that achieves the elimination of ringing was used. The filtered signals for the X, Y and Z leads were integrated into a vectormagnitude complex by the usual formula, $M = \sqrt{X^2 + Y^2 + Z^2}$. Onset and offset of QRS were determined by computer algorithm, by respective forward and backward searches noise level to determine the midpoint of the 5-ms segment in which the average signal exceeds the noise level mean ±3 standard deviations.

Measurements included the total duration of the integrated QRS complex, the total duration of the terminal QRS potentials that are less than 40 μV RMS, the total duration of potentials in terminal QRS less than 25 μV RMS, the RMS of the total voltage in the last 40 and the last 50 ms of the QRS.

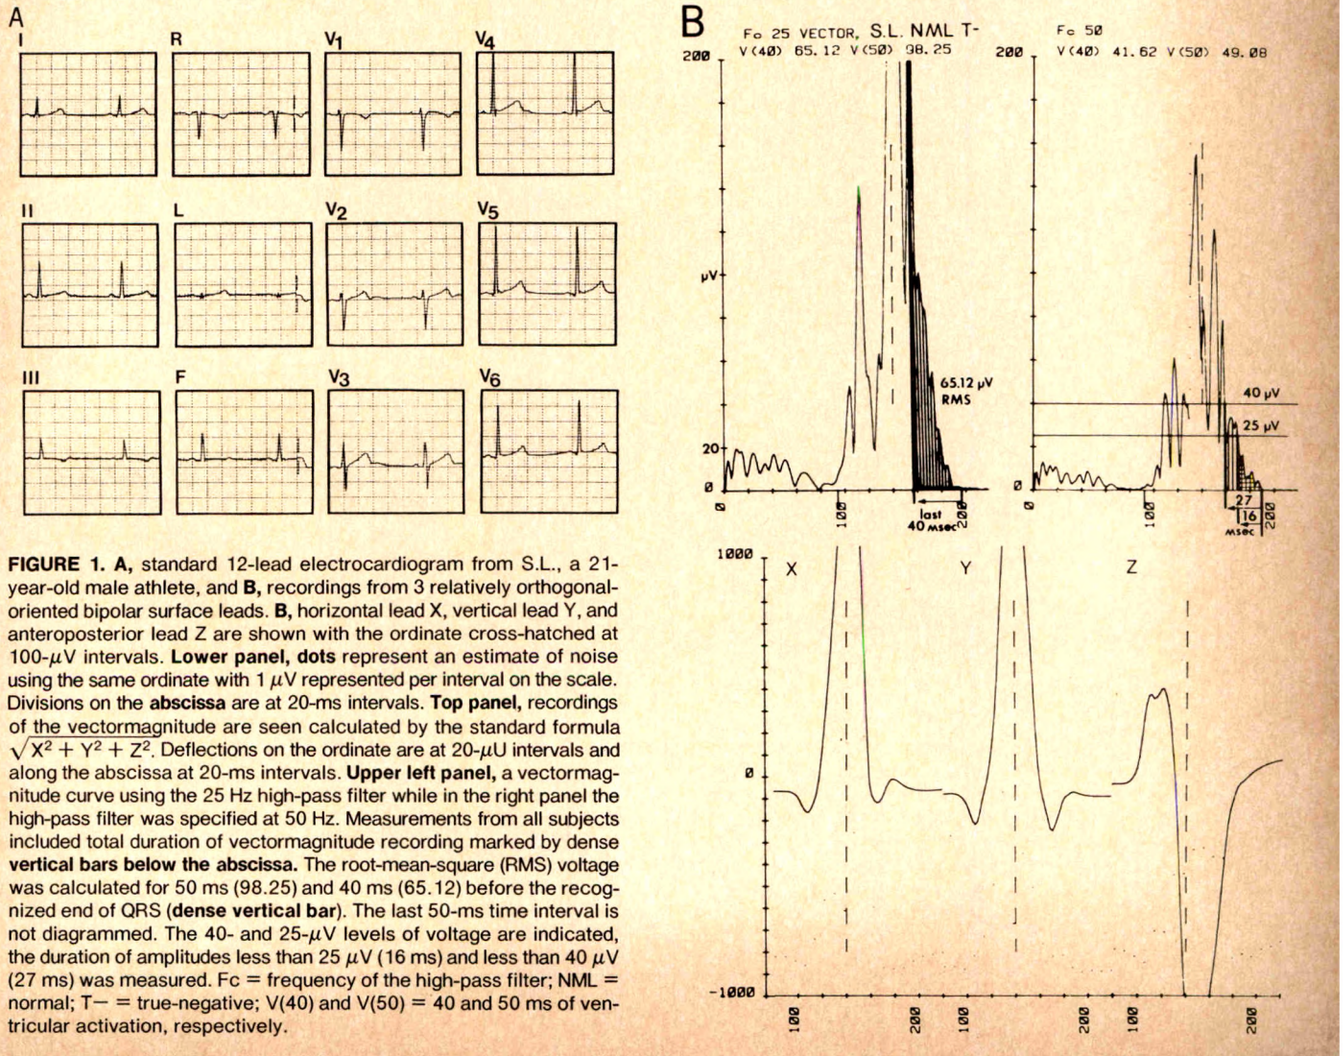

FIGURE 1. A, standard 12-lead electrocardiogram from S.L., a 21-year-old male athlete, and **B,** recordings from 3 relatively orthogonal-oriented bipolar surface leads. **B,** horizontal lead X, vertical lead Y, and anteroposterior lead Z are shown with the ordinate cross-hatched at 100-μV intervals. **Lower panel, dots** represent an estimate of noise using the same ordinate with 1 μV represented per interval on the scale. Divisions on the **abscissa** are at 20-ms intervals. **Top panel,** recordings of the vectormagnitude are seen calculated by the standard formula $\sqrt{X^2 + Y^2 + Z^2}$. Deflections on the ordinate are at 20-μU intervals and along the abscissa at 20-ms intervals. **Upper left panel,** a vectormagnitude curve using the 25 Hz high-pass filter while in the right panel the high-pass filter was specified at 50 Hz. Measurements from all subjects included total duration of vectormagnitude recording marked by dense **vertical bars below the abscissa.** The root-mean-square (RMS) voltage was calculated for 50 ms (98.25) and 40 ms (65.12) before the recognized end of QRS (**dense vertical bar**). The last 50-ms time interval is not diagrammed. The 40- and 25-μV levels of voltage are indicated, the duration of amplitudes less than 25 μV (16 ms) and less than 40 μV (27 ms) was measured. Fc = frequency of the high-pass filter; NML = normal; T− = true-negative; V(40) and V(50) = 40 and 50 ms of ventricular activation, respectively.

Results

A normal ECG, X, Y and Z leads and a vectormagnitude record are shown in Figures 1A and B from a 21-year-old athlete. The 12-lead standard ECG is normal. Note the relatively sharp decay after the intrinsicoid deflection and the relative lack of QRS notching in the X, Y, and Z leads; also note the very rapid decline toward the terminal end of the QRS in the vectormagnitude record. The last 40 ms of the vectormagnitude recording reveals RMS voltage values of 85 and 42 μV at both HPF frequencies, values well within the normal range. Voltage during the last 40 ms of the QRS recorded with the 25 Hz HPF was considered normal if it was at least 25 μV RMS. Using the 50 Hz HPF, voltage of at least 18 μV RMS was considered normal. Figure 2 is an example of a false-positive result from a normal 29-year-old soccer player whose RMS voltage during the last 40 ms was 22.33 and 16.01 μV, respectively. A 22-year-old male athlete had the lowest voltage in the group during the 40 ms at 25 Hz—12.69 μV RMS. As was the case with all normal subjects, the standard direct writer ECGs were normal in all 3 false-positive patients with QRS duration not in excess of 100 ms. The amplified and filtered vectormagnitude records exceeded 100 ms in 4 subjects in the normal group, 2 of whom had late potentials. Specifically, none revealed intraventricular conduction defects and none had an rSr' pattern in lead V_1.

Using the 25 Hz HPF, the correlation in the group of 50 normal subjects between total QRS duration and the duration of terminal potentials less than 40 μV was poor ($r = 0.362$), as was the correlation with terminal potentials less than 25 uV ($r = 0.453$). The correlation did not improve with 50 Hz HPF.

We also examined the correlation between total QRS duration in the normal subjects and the RMS voltage during the last 40 and 50 ms at 50 Hz. A negative correlation resulted of 0.569 and 0.480, respectively. However, when the correlation was tested between QRS duration and terminal voltage using the 25 Hz HPF as indicated in Figure 3, the negative correlation was somewhat higher during both the last 40 ms ($r = -0.678$) and during the last 50 ms ($r = -0.684$).

For purposes of classification we termed as true-negative any normal subject who had 25 μV or greater in the last 40 ms of the QRS using the 25 Hz HPF. Forty-seven of 50 subjects met this criterion. Three normal subjects failed to meet this criterion and demonstrated late potentials. No other distinguishing fea-

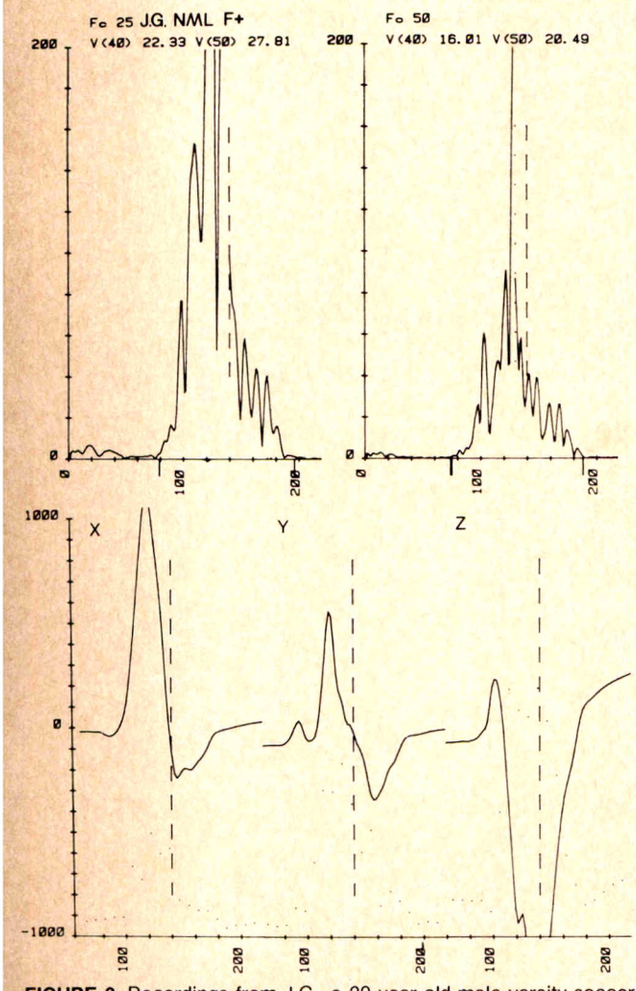

FIGURE 2. Recordings from J.G., a 29-year-old male varsity soccer player, whose voltage during the last 40 ms of the QRS was 22.33 μV root-mean-square with 25 Hz high-pass filter and 16.01 μV root-mean-square with 50 Hz high-pass filter. Contrast the sharp decline in the vectormagnitude record in Figure 1 with the more prolonged lower amplitude higher frequencies in this figure. Further, note the slight increase in mid-QRS notching and slurring visible in the X, Y and Z leads in this illustration, which is less impressive in Figure 1. While the standard 12-lead electrocardiogram did not reveal a QRS greater than 100 ms, the pattern was not that of an intraventricular conduction defect, nor did V_1 show an rSr' pattern, although a relatively prominent S wave in X is noted. F+ = false-positive; other abbreviations as in Figure 1.

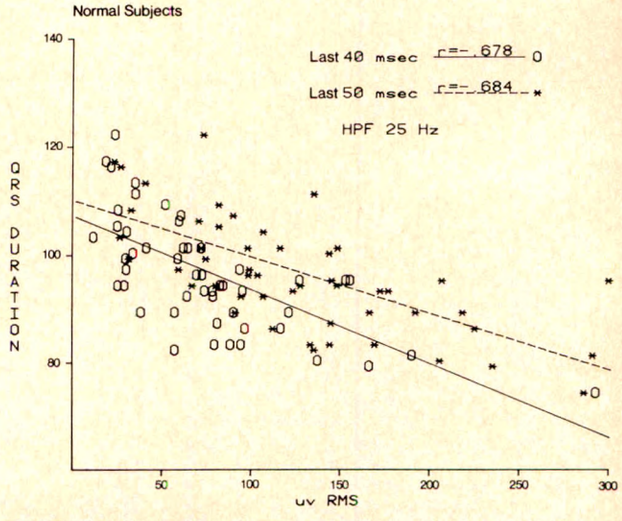

FIGURE 3. With the high-pass filter (HPF) specification at 25 Hz, negative correlation within the normal subject group between QRS duration and the root-mean-square (RMS) of the voltage during the last 40 (**solid regression line** $r = -0.678$) and the last 50 ms (**dashed regression line** $r = -0.684$).

TABLE I Late Potentials in Normal Subjects and in Patients with Ventricular Tachycardia Unrelated to Infarction*

	25 Hz HPF		
	Normal Subjects	VT Patients	p
ms QRS	96.86 ± 1.49	118.36 ± 10.16	NS
μV last 40 ms	76.15 ± 7.31	46.26 ± 9.30	<0.025
μV last 50 ms	126.93 ± 9.61	72.22 ± 13.61	<0.01
ms term. pot. <40 μV	20.80 ± 1.59	33.72 ± 4.87	<0.05
ms term. pot. <25 μV	14.86 ± 1.04	19.27 ± 2.90	NS

* Using the 25 Hz high-pass filter, this table shows results of group comparisons using the 5 measured parameters characterizing late potentials. All values are expressed as mean ± standard error of the mean. Significant differences were established between the normal subjects and the subset with ventricular tachycardia when voltage during the last 40 and 50 ms was considered and when the duration of terminal potentials shorter than 40 μV was considered.

HPF = high-pass filter; NS = not significant; term. pot = terminal potential; VT = ventricular tachycardia.

tures were identified, either clinically or analytically in these subjects. Thus, 94% true-negative and only 6% false-positive responses were seen.

An example of a true-positive response from the VT group is from a patient with hypertensive etiologic factors who demonstrated low voltages of 13.36 μV RMS and 9.11 μV RMS at 40 and 50 Hz, respectively (Fig. 4). A false-negative record from a patient with mitral valve prolapse is illustrated in Figures 5A and B. This patient had occasional sustained VT as well as recurrent nonsustained VT. The coronary arteriogram was normal. Note the sharp decay of the vectormagnitude record with a normal terminal voltage of 85.9 μV and 34.48 μV RMS with 25 and 50 Hz HPF, respectively.

Thus, in the VT group, 5 of 11 patients (or only about 45%) met the true-positive criterion: voltage during the last 40 ms of QRS was under 25 μV RMS (although a sixth patient demonstrated only 25.71 μV RMS). Both patients with standard QRS durations in excess of 120 ms also had low-amplitude late potentials.

Table I lists the comparison of group mean ± standard error of the mean of the 5 parameters measured in the normal group and in the VT group. Unlike other comparative experiences, the total duration of QRS in the normal group and in the VT group did not show statistically significant differences; however, the trend toward a difference is obvious. Although the means are quite different, the reason for lack of significance appears to be a wide standard deviation among the patients with VT. A significant group difference was demonstrated in the voltage during the last 40 and 50 ms and in the duration of terminal potentials using the 25 Hz HPF. Using the 50 Hz HPF, significant differences were shown for the voltage during the last 40 and 50 ms, but not in the other 3 parameters measured (Table II).

Although it was meaningful to make group comparisons, for a diagnostic test to be clinically useful, it should accurately specify a person as belonging to 1 or another diagnostic category. In this light, the overall predictive accuracy of late potentials was 85% using the

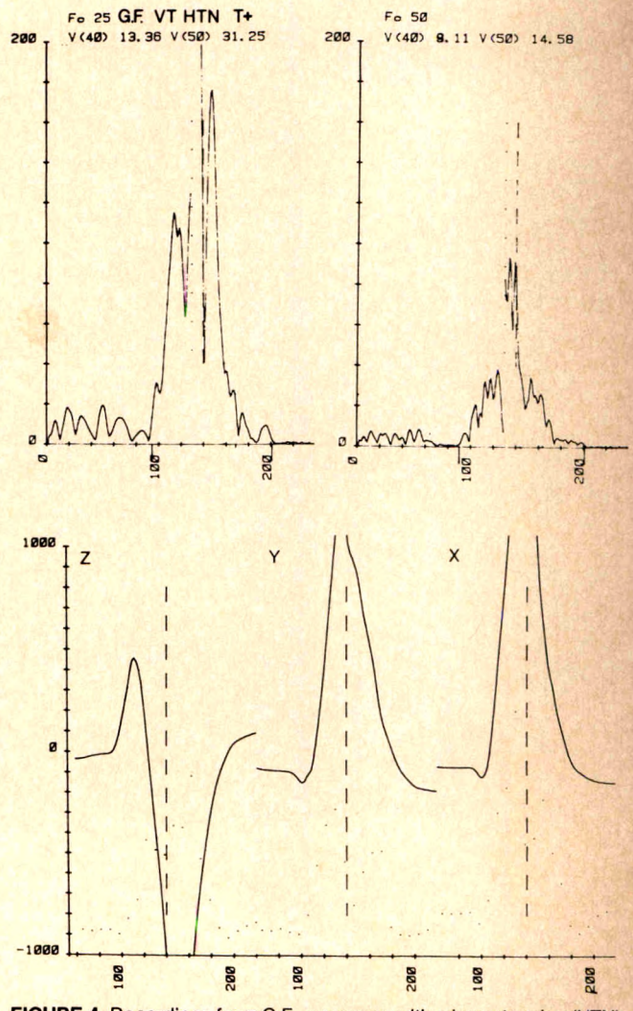

FIGURE 4. Recordings from G.F., a woman with a hypertension (HTN) as a cause of heart disease, who had repeated runs of ventricular tachycardia (VT) and who is representative of our true-positive patients with low-amplitude late potentials of 13.36 and 9.11 μV root-mean-square with 25 and 50 Hz high-pass filter, respectively. Note the trailing out of the low-amplitude tail during the terminal portion of ventricular activation. T+ = true-positive; other abbreviations as in Figure 1.

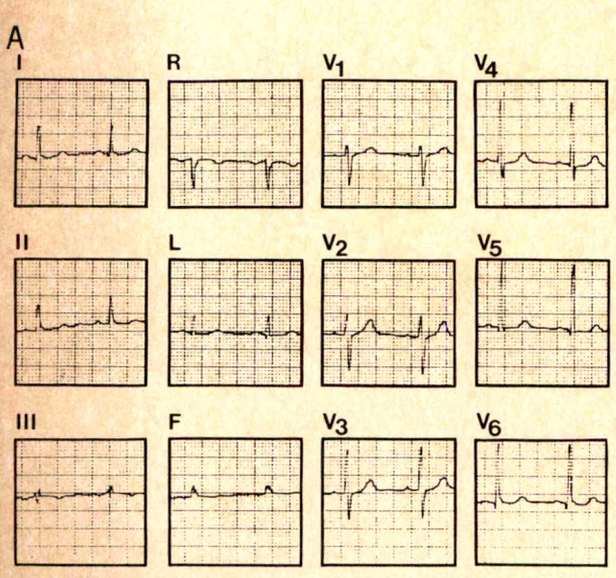
single 25 μV criterion as mentioned (i.e., voltage at least 25 μV for normal subjects and less than 25 μV for patients with VT using the 25 Hz HPF). However, this criterion reflects the good performance in the larger normal group, rather than an equally high positive predictive accuracy.

Using all 5 parameters tested, we sought single values that would better separate the normal subject from the patient with VT. Table III demonstrates that when the 50 Hz HPF was used, 75% of the patients with VT had a potential less than 25 μV RMS for a duration of at least 26 ms, whereas 84% of the normal subjects had a terminal potential less than 25 μV RMS for durations uniformly less than 26 ms. Computer searches at 1-ms intervals up and down the scale from 26 ms resulted in improvement in individual recognition in 1 category, but inevitably a more than equivalent loss in recognition ability in the other category. With use of the 25 Hz HPF, performance of single-point separation of patients with nonischemic, nonsustained VT from normal subsets was less effective.

Disappointed that we were not seeing the degree of late potential discrimination previously encountered when patients with VT secondary to coronary artery disease and MI were studied, we turned our attention to looking at the heart size in this group of patients with VT from multiple, noninfarction causes. An interesting relation emerged (Table IV). The patients with VT, who also had cardiothoracic ratios in excess of 0.5 in the 72-inch upright posteroanterior roentgenogram of the chest, uniformly revealed the lower terminal voltage. Conversely, patients with VT with normal-sized hearts had the higher terminal voltages. There was a 34.2 μV RMS jump that occurred between the patient with the highest voltage with cardiomegaly and the patient with the lowest voltage with a normal cardiac silhouette. This latter patient had the largest heart (meeting the radiographic criterion for normal) and barely met the terminal potential magnitude criterion of normal. The etiology was cardiomyopathic. Because alcohol consumption was not a consideration, and because he had a severe viral infection before an acute onset of ventricular rhythm, the cause was presumed to be viral. Cultures and titers were not obtained. The left ventricular ejection fraction derived from catheterization data was 28% and the coronary arteries were normal. The standard ECG did not reveal left ventricular enlargement.

Discussion

Recordings with the 50 Hz HPF were found to be only slightly more reproducible on successive days than they were with the 25 Hz HPF. The optimal single point of



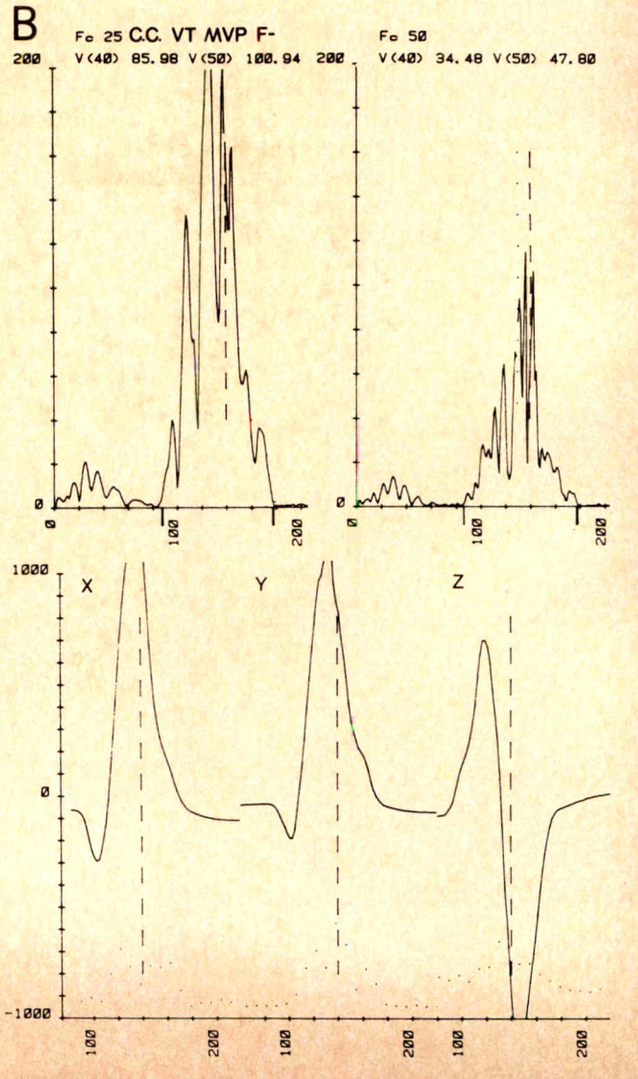


FIGURE 5. A, electrocardiogram, and **B,** X, Y and Z leads and vector-magnitude record from C.C., a patient representative of the false-negatives with sustained ventricular tachycardia and a diagnosis of mitral valve prolapse (MVP). Coronary arteriography revealed no significant coronary artery disease. Note the normal routine electrocardiogram and the very sharp decline of QRS with the terminal voltage well above the 25 μV RMS level which was 85.9 μV with the 25 Hz high-pass filter, and 34.48 μV RMS with the 50 Hz high-pass filter. A relatively normal set of orthogonal leads X, Y and Z, as well as the filtered leads, was recorded. F— = false-positive; other abbreviations as in Figure 1.

TABLE II Late Potentials in Normal Subjects and in Patients with Ventricular Tachycardia Unrelated to Infarction*

	50 Hz HPF		
	Normal Subjects	VT Patients	p
ms QRS	95.38 ± 1.53	110.0 ± 11.03	NS
μV last 40 ms	40.77 ± 5.86	20.10 ± 4.94	<0.025
μV last 50 ms	60.08 ± 6.71	27.23 ± 5.65	<0.005
ms term. pot. <40 μV	28.43 ± 1.88	50.29 ± 14.36	NS
ms term. pot. <25 μV	22.08 ± 1.66	35.43 ± 8.25	NS

* Group comparisons using the 5 parameters measured from data recorded with the 50 Hz high-pass filter (HPF). Groups are statistically different when voltage during the last 40 or 50 ms of QRS were considered.

Abbreviations as in Table I.

TABLE III Late Potentials in Normal Subjects and in Patients with Ventricular Tachycardia Unrelated to Infarction*

	Correct Classification 50Hz HPF	
	Patients with Nonsustained VT (%)	Normal Subjects (%)
Last 40 ms	57 <20 μV	86 ≥20 μV
Last 50 ms	57 <30 μV	94 ≥30 μV
Last 40 ms	57 <15 μV	94 ≥15 μV
Last 50 ms	57 <25 μV	94 ≥25 μV
QRS duration	57 >110 ms	100 ≤110 ms
Duration <40 μV term. pot.	72 ≥30 ms	66 <30 ms
Duration <40 μV term. pot.	57 ≥37 ms	90 <37 ms
Duration <25 μV term. pot.	75 ≥26 ms	84 <26 ms

* Using the 5 parameters tested, single values were sought that would separate the normal subset from the patient with ventricular tachycardia. The 50 Hz high-pass filter was slightly more effective than the 25 Hz high-pass filter in achieving the best group separation. The most effective point of separation was the 26-ms duration of terminal potentials shorter than 25 μV. In the normal subjects, 84% had terminal potentials shorter than 25 μV that lasted under 26 ms, whereas in 75% of patients with VT the duration was at least 26 ms. See text.

Abbreviation as in Table I.

discrimination between the normal subject and the patient with nonsustained VT was found with the 50 Hz HPF (Table III). Group differences were seen with both HPF frequencies, but the most significant group difference (i.e., the voltage during the last 50 ms) was with the 50 Hz filter (Table II). In comparing effectiveness of discrimination of 2 different filter frequencies, 1 consideration should be recognized. For example, if frequency content between 25 and 50 Hz is abundantly represented at the end of QRS, the duration of the recording may be slightly shorter with the 50 than with the 25 Hz HPF. In comparing the results of 1 study with another, filter frequencies that vary between studies more widely than those represented in this study could become a major consideration.

A ready explanation was not forthcoming for the 3 normal subjects who revealed late potentials less than 25 μV RMS during the last 40 ms of the QRS. Whereas the hearts of these 3 subjects (all of whom are varsity soccer players) were at the upper limits of normal, none exceeded a cardiac thoracic ratio of 0.5. One subject was black, 1 was white, and 1 was Hispanic of South American Indian extraction.

We thought it logical to attempt a correlation between the total QRS duration and the duration of late potentials. We reasoned that because total QRS duration tends to increase in patients after MI, often with some degree of conduction delay in the low-amplitude terminal QRS, it might also relate to a parallel spectrum of low-amplitude terminal potential durations in normal subjects. This was not found to be the case as evidenced by the low r values. Although the ability of terminal potential amplitude or duration to distinguish the abnormal from the normal group was quite good, the ability to correctly specify persons within the VT group was much less impressive. All subjects had very symptomatic, recurrent episodes of nonsustained VT, although 1 also had an occasional episode of sustained VT, lasting longer than 30 seconds. The fact that only 2 subjects in the present study had a history of MI (and these events occurred in the remote past) suggests that this group of subjects with VT is basically very different from groups in earlier studies in which ischemic disease was implicit and the tachycardias were sustained.

The precise ultrastructural and functional relations of surface recorded late potentials, notches and slurs, and the fragmented epicardial electrogram remain unclear and is a rich field for investigation. Perhaps the most significant observation in this study is that, for whatever reason, the lower terminal voltage was clearly concentrated in patients with larger hearts. This observation may bear a relation to an earlier finding, that even in the absence of infarction, ventricular enlargement from any cause is also associated with an alteration in ventricular activation manifested by an increase in QRS notching.[7,8]

Correspondence between fragmented electrograms recorded directly from the heart and late potentials

TABLE IV Relations of Heart Size to Late Potentials in Patients with Ventricular Tachycardia

VT	↑ Heart CXR	Last 40 ms μV RMS
Hypertension	+	13.36
CAD	+	17.77
CAD	+	21.14
CAD	+	21.92
MVP	+	24.30
Cardiomyopathy	+	25.71
Mellaril	0	59.93
CAD	0	64.34
AVD	0	81.39
MVP	0	85.98
Cardiomyopathy	0	93.02
	25 Hz HPF	

The most likely cause of heart disease is listed for each patient. Two of the patients with coronary artery disease were so diagnosed because of a history of remote myocardial infarction. One other had greater than 50% diameter encroachment of a single coronary artery, and a fourth had minimal plaque formation only. Note the 34.22-μV difference between the patient with an enlarged heart with the highest voltage (25.71) and the patient with a normal-sized heart with the lowest (59.93). AVD = aortic valve disease; CAD = coronary artery disease; CXR = chest x-ray; HPF = high-pass filter; HTN = hypertension; MVP = mitral valve prolapse; RMS = root-mean-square; VT = ventricular tachycardia; + = yes; 0 = no.

recorded from the body surface has been pointed out by Simson et al.[9] Gardner et al[10] explored the nonuniform anisotropic border zone in the canine heart and pointed out that transmembrane action potentials may be normal at this time, though conduction remains very slow, presumably because the junctions between surviving myocardial fibers in the healed infarcts are very sparse. With premature stimulation, conduction block readily occurs, and this may cause reentry. These investigators emphasize that the structure of infarcts may be as important as the characteristics of the transmembrane potentials of the surviving muscle fibers in causing reentrant excitation. Along the same line, also in canine infarcts, evidence was presented that slow conduction alone does not cause fragmented activity. The appearance of fractionated electrograms in 2-week-old infarction seems to coincide with the increase in connective tissue in the epicardial border zone, which separates the myocardial fibers and eventually distorts the orientation. These investigators believe that the individual components of the fragmented electrograms most likely represent asynchronous electrical activity in separate bundles of surviving muscle under the recording electrode. They conclude that the anatomic substrate for reentry is present where fragmented electrograms can be recorded, because these electrograms indicate slow, inhomogeneous conduction. However, they emphasize that fragmented electrograms are probably found wherever myocardial fibers are separated by connective tissue, whether or not reentry occurs in the region.[10]

Can these very fundamental insights be applied to explain why, in this study of nonischemic patients with VT, surface recorded terminal potentials of low amplitude appeared only when cardiomegaly was present, but were not present in subjects with normal-sized hearts? A possibility worth considering is that, because fragmented electrograms are found when myocardial fibers are separated by connective tissue, in the patient with a noninfarcted heart, a critical degree of connective tissue separation must occur as a result of gradual cardiac enlargement, before late potentials can be recorded by surface techniques, even with the use of signal averaging. Conversely, after MI in the patient with ischemic heart disease, such fibrotic separation may occur well before marked enlargement occurs.

In conclusion, much basic work must be done to explain the relations of the various markers of alteration of the process of ventricular excitation.

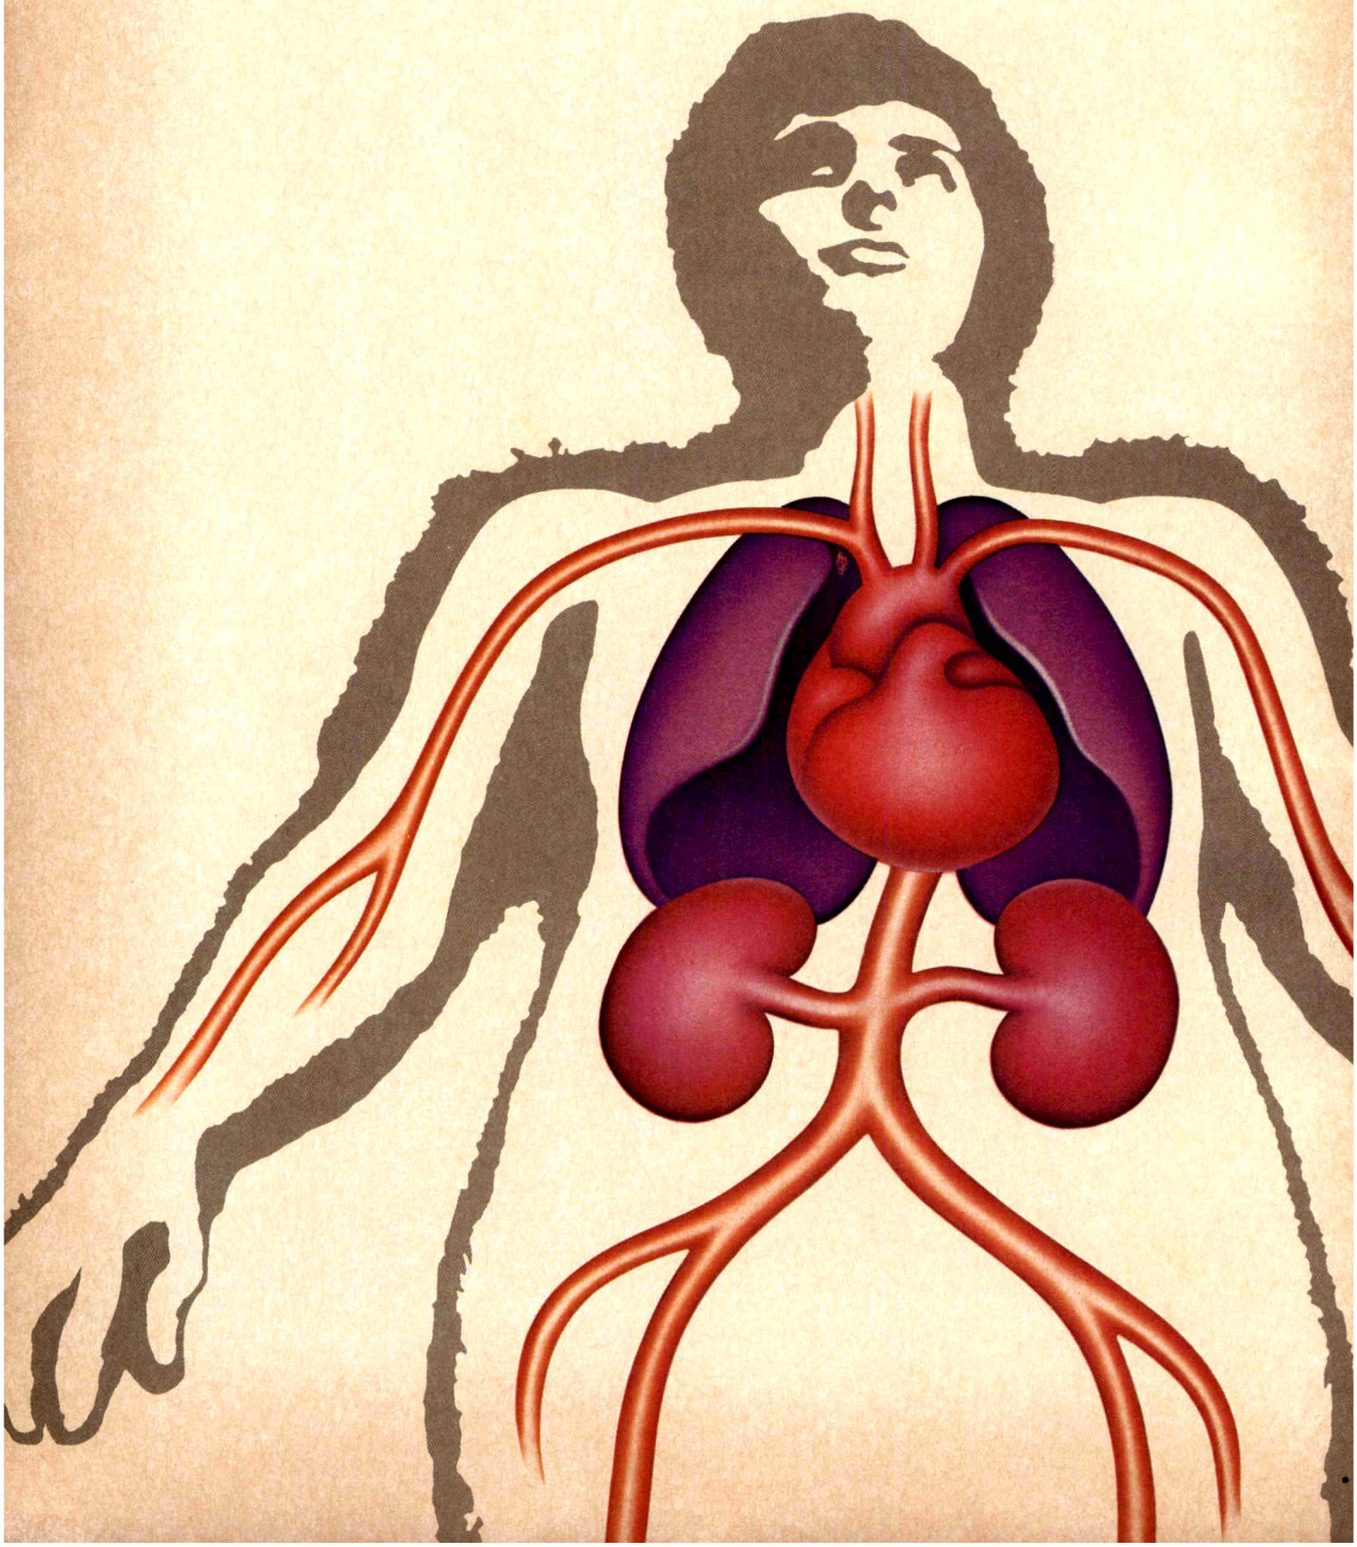
Unlike any single-entity antihypertensive you've ever used.



Schering

Normodyne® (labetalol HCl) is a unique single-entity agent. It acts as a beta blocker as well as an alpha$_1$ vasodilator, offering the advantages of both while avoiding many of the disadvantages. Beyond beta blockers, it also acts as a vasodilator to lower blood pressure. Beyond vasodilators, it acts as a beta blocker to blunt excessive cardiac response to exercise in hypertensives.

- Unsurpassed efficacy in mild to moderate hypertension.
- Useful in a wide diversity of patient types.
- Favorable side-effects profile.
- A demonstrated safety profile.
- Well documented in hundreds of clinical studies.
- Millions of patients treated worldwide.
- Compliance-enhancing b.i.d. dosage.

The unique single-entity blocker/dilator

NORMODYNE®

Tablets (labetalol HCl)

Please see brief summary of prescribing information at the end of this advertisement.

Differences that direct patient benefits

Efficacy

A comprehensive review of worldwide literature has shown the efficacy of Normodyne® (labetalol HCl) to be unsurpassed in mild to moderate hypertension. Comparative drugs in these studies included beta blockers, alpha adrenergic blocking agents and centrally acting antihypertensives.

- Effective alone or in combination with a diuretic.
- Prompt onset of action, usually within two hours.[1,2]
- Easily titrated to achieve desired effect.
- No tolerance development as shown in clinical studies up to one year.

Convenient b.i.d. dosage.

Initiate therapy with one-half (1/2) scored 200 mg tablet b.i.d. Instruct patient to continue this regimen until the first follow-up visit, which should occur in three to seven days. Patient should be told to phone about any problems or other concerns.

Versatility

Normodyne® (labetalol HCl) may be used in a wide diversity of patients, including:

The elderly

In a year-long study,[3] Normodyne lowered blood pressure smoothly and safely in patients with a mean age of 66 without causing problems of frequent concern when treating hypertension in the elderly. (Some patients may be maintained at lower doses.)

Active hypertensives Normodyne does not impede cardiac response to sports or strenuous activity. It does not adversely affect blood flow to vital organs and produces a low incidence of fatigue and drowsiness.

Black patients Normodyne has been shown to be effective in reducing and controlling hypertension in black patients.[4]

translate into... and fewer limitations.

Schering

Side effects

Normodyne® (labetalol HCl) has a favorable side-effects profile.*

Unlike propranolol, a conventional beta blocker, Normodyne produces a low incidence of

- fatigue (5%)
- bradycardia (none reported in controlled clinical trials)
- cold extremities (none reported in controlled clinical trials)

Unlike vasodilators, a low incidence of

- orthostatic hypotension (1%)
- tachycardia (none reported in controlled clinical trials)
- headaches (2%)

Most adverse effects are mild, transient and occur early in the course of treatment. In 3-to-4 month controlled clinical trials, the most common side effects noted in treating mild to moderate hypertension with Normodyne include dizziness (11%), nausea (6%), and fatigue (5%). Dyspepsia (3%) and nasal stuffiness (3%) occurred to a lesser degree.

Safety

Normodyne® (labetalol HCl) has a demonstrated safety profile.

Co-existing COPD.[5,6] Patients with non-allergic bronchospasm should, in general, not receive beta blockers. Normodyne may be used with caution, however, in patients who do not respond to, or cannot tolerate, other antihypertensive agents.†

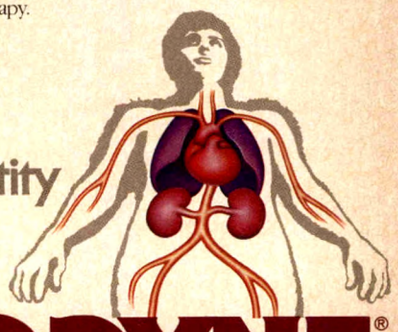
Co-existing controlled CHF.[7] Although beta blockers as a class should be avoided in *overt* congestive heart failure, Normodyne can be used, if necessary, in patients with a history of heart failure who are well compensated.

Co-existing CAD. In patients with hypertension and coronary artery disease, Normodyne reduced blood pressure, maintained cardiac output and blunted excessive response to exercise.[8-11]††

Vital organs & serum lipids. Normodyne did not adversely affect perfusion of brain, heart, lungs and kidneys. Nor was renal function in renally impaired patients or in those with normal kidney function adversely affected.[12] Normodyne also did not adversely affect serum levels of HDL-cholesterol, total cholesterol, or triglycerides.

† It is prudent, if Normodyne is used in these patients, to use the smallest effective dose so that inhibition of endogenous or exogenous beta-agonists is minimized.

†† Patients should be advised to consult their physicians before discontinuing therapy.



The unique single-entity blocker/dilator for hypertension

NORMODYNE®

Tablets (labetalol HCl)

Please see brief summary of prescribing information and references at the end of this advertisement.

NORMODYNE®
brand of labetalol hydrochloride
Tablets
BRIEF SUMMARY

INDICATIONS AND USAGE
NORMODYNE (labetalol HCl) Tablets are indicated in the management of hypertension. NORMODYNE Tablets may be used alone or in combination with other antihypertensive agents, especially thiazide and loop diuretics.

CONTRAINDICATIONS
NORMODYNE (labetalol HCl) Tablets are contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia. (See **WARNINGS.**)

WARNINGS
Cardiac Failure Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, NORMODYNE (labetalol HCl) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal Angina pectoris has not been reported upon labetalol HCl discontinuation. However, hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered NORMODYNE (labetalol HCl), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, NORMODYNE (labetalol HCl) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue NORMODYNE (labetalol HCl) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis and emphysema) Patients with bronchospastic disease should, in general, not receive beta-blockers. NORMODYNE may be used with caution, however, in patients who do not respond to, or cannot tolerate, other antihypertensive agents. It is prudent, if NORMODYNE is used, to use the smallest effective dose, so that inhibition of endogenous or exogenous beta-agonists is minimized.

Pheochromocytoma Labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heart beat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions**).

PRECAUTIONS
General *Impaired Hepatic Function* NORMODYNE (labetalol HCl) Tablets should be used with caution in patients with impaired hepatic function since metabolism of the drug may be diminished.

Jaundice or Hepatic Dysfunction On rare occasions, labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately, should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients
As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. While no incident of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with NORMODYNE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with NORMODYNE Tablets should consult a physician at any sign of impending cardiac failure. Also, transient scalp tingling may occur, usually when treatment with NORMODYNE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests
As with any new drug given over prolonged periods, laboratory parameters should be observed over regular intervals. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions
In one survey, 2.3% of patients taking labetalol HCl in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions
The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C
Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the maximum recommended human dose (MRHD), respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects
Infants of mothers who were treated with labetalol HCl for hypertension during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of 2 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery
Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers
Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when NORMODYNE Tablets are administered to a nursing woman.

Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Most adverse effects are mild, transient and occur early in the course of treatment. In controlled clinical trials of 3 to 4 months duration, discontinuation of NORMODYNE (labetalol HCl) Tablets due to one or more adverse effect was required in 7% of all patients. In these same trials, beta-blocker control agents led to discontinuation in 8 to 10% of patients, and a centrally acting alpha-agonist in 30% of patients.

The incidence rates of adverse reactions listed in the following table were derived from multicenter controlled clinical trials, comparing labetalol HCl, placebo, metoprolol and propranolol, over treatment periods of 3 and 4 months. Where the frequency of adverse effects for labetalol HCl and placebo is similar, causal relationship is uncertain. The rates are based on adverse reactions considered probably drug-related by the investigator. If all reports are considered, the rates are somewhat higher (e.g., dizziness 20%, nausea 14%, fatigue 11%), but the overall conclusions are unchanged.

	Labetalol HCl (N = 227) %	Placebo (N = 98) %	Propranolol (N = 84) %	Metoprolol (N = 49) %

The adverse effects were reported spontaneously and are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, i.e., a group excluding patients with bronchospastic disease, overt congestive heart failure, or other contraindications to beta-blocker therapy.

Clinical trials also included studies utilizing daily doses up to 2400 mg in more severely hypertensive patients. Certain of the side effects increased with increasing dose as shown in the table below which depicts the entire U.S. therapeutic trials data base for adverse reactions that are clearly or possibly dose related.

Labetalol HCl Daily Dose (mg)	200	300	400	600
Number of Patients	522	181	606	608

Edema	1	0	1	2	2

In addition, a number of other less common adverse events have been reported in clinical trials or the literature:

Cardiovascular Syncope. *Central and Peripheral Nervous Systems* Paresthesias, most frequently described as scalp tingling. In most cases, it was mild, transient and usually occurred at the beginning of treatment. *Collagen Disorders* Systemic lupus erythematosus; positive antinuclear factor (ANF). *Eyes* Dry eyes. *Immunological System* Antimitochondrial antibodies. *Liver and Biliary System* Cholestasis with or without jaundice. *Musculo-Skeletal System* Muscle cramps; toxic myopathy. *Respiratory System* Bronchospasm. *Skin and Appendages* Rashes of various types, such as generalized maculo-papular; lichenoid; urticarial; bullous lichen planus; psoriaform; facial erythema; Peyronie's disease; reversible alopecia. *Urinary System* Difficulty in micturition, including acute urinary bladder retention.

Following approval for marketing in the United Kingdom, a monitored release survey involving approximately 6,800 patients was conducted for further safety and efficacy evaluation of this product. Results of this survey indicate that the type, severity, and incidence of adverse effects were comparable to those cited above.

Potential Adverse Effects
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents.

Central Nervous System Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular Intensification of AV block.
See **CONTRAINDICATIONS.**

Allergic Fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic Agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura.

Gastrointestinal Mesenteric artery thrombosis; ischemic colitis.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl.

Clinical laboratory tests: There have been reversible increases of serum transaminases in 4% of patients treated with labetalol HCl and tested, and more rarely, reversible increases in blood urea.

OVERDOSAGE
Overdosage with NORMODYNE (labetalol HCl) Tablets causes excessive hypotension which is posture sensitive, and sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve the blood supply to the brain. The following additional measures should be employed if necessary: *Excessive bradycardia* — administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. *Cardiac failure* — administer a digitalis glycoside and a diuretic. *Hypotension* — administer vasopressors, e.g., norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. *Bronchospasm* — administer a beta$_2$-stimulating agent and/or a theophylline preparation.

Gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 gm/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

Ventricular Arrhythmia Induced by Programmed Ventricular Stimulation After Acute Myocardial Infarction

PIETRO SANTARELLI, MD, FULVIO BELLOCCI, MD, FRANCESCO LOPERFIDO, MD, MARIO MAZZARI, MD, ROCCO MONGIARDO, MD, ANNIBALE S. MONTENERO, MD, UGO MANZOLI, MD, and PABLO DENES, MD

The prevalence, characteristics and clinical significance of ventricular electrical instability with programmed ventricular stimulation was studied in 50 hemodynamically stable patients 17 to 40 days after acute myocardial infarction (AMI) using double extrastimuli at 2- and 10-mA intensity and from 2 right ventricular sites. Ventricular electrical instability was defined as induction of 10 or more consecutive intraventricular reentrant beats. Of 50 patients, 23 (46%) had ventricular electrical instability (10 of these had sustained ventricular tachycardia [VT] induced). No significant differences were observed between patients with and without ventricular electrical instability with respect to age, site of AMI, coronary prognostic index, maximal level of CK, number of narrowed coronary arteries and presence of severe wall motion abnormalites. During a mean follow-up of 11.2 months no patient died suddenly. During repeated Holter recordings patients with ventricular electrical instability had a higher incidence of nonsustained VT than did patients without ventricular electrical instability.

(Am J Cardiol 1985;55:391–394)

Previous studies[1–3] have presented evidence that after acute myocardial infarction (AMI) programmed ventricular stimulation is a sensitive and specific method for identification of patients at high risk of having ventricular tachycardia (VT) or sudden death. We report the results of a prospective study of programmed ventricular stimulation in the late hospital phase of AMI. Specifically we studied (1) the prevalence and the characteristics of the induced ventricular arrhythmias, (2) the correlation between the induced ventricular arrhythmias and the clinical, Holter monitoring and angiographic findings, and (3) the results of follow-up.

Methods

Patients: One hundred thirty-eight patients were admitted to the coronary care unit with documented AMI from October 1982 to October 1983. Nineteen of these 138 patients died before discharge. Of the remaining 119 patients, 50 (49 men and 1 woman, mean age [± standard deviation] 53 ± 9 years), were entered in the study 25 ± 5 days (range 17 to 40) after AMI. Criteria for inclusion in the study were: (1) documented (clinical history, serial electrocardiogram and serum enzyme changes) and recent (less than 6 weeks) AMI; (2) absence of intractable congestive heart failure or cardiogenic shock; (3) written informed consent; and (4) absence of significant (more than 50% narrowing) left main coronary artery narrowing and rheumatic valvular heart disease.

The study protocol consisted of: (1) coronary angiography and left ventriculography, (2) electrophysiologic study, including programmed ventricular stimulation at least 30 minutes after coronary angiography, and (3) 24-hour Holter monitoring the day before the invasive studies.

Ambulatory electrocardiographic monitoring: Twenty-four-hour Holter monitoring was performed 24 to 36 hours before cardiac catheterization and after all antiarrhythmic drugs had been withdrawn for a period of 5 half-lives. The recording system (Hittman Comp-Act IV) allowed simultaneous recording of 2 electrocardiographic leads (V_1 and V_5). An audiovisual scanning technique was used to review tape records. The interpretation was done by physicians who reviewed direct printouts of each grade of premature ventricular beats. The frequency, configuration and timing of spontaneous premature ventricular beats were classified according to the Lown grading system.[4] During follow-up, the 24-hour Holter monitoring was repeated.

CCU = coronary care unit; CK = creatine kinase; MI = myocardial infarction; NS = not significant; SD = standard deviation; VEI = ventricular electrical instability; VF = ventricular fibrillation; VT = ventricular tachycardia.

Cardiac catheterization: Sixty patients underwent cardiac catheterization using a femoral approach. A maximum of 8 ml of 1% xylocaine was used as local anesthetic. Two quadripolar catheters (No. 6Fr or 7Fr) were introduced into the femoral vein. Left-sided cardiac catherization was performed using the Judkins technique and included single-plane left ventriculography in the right anterior oblique position, and coronary angiography. Narrowing of the left main coronary artery less than 50% in diameter or severe angina during catheterization led to termination of the procedure.

Electrophysiologic study: Of the 119 patients who entered the study, 52 refused consent and 7 had severe congestive heart failure or cardiogenic shock, or both. Sixty patients underwent cardiac catheterization, and 50 of these had electrophysiologic study at least 30 minutes after angiography. Ten patients were excluded: 3 with left main disease, 4 with prolonged chest pain during angiography and 3 with valvular heart disease.

The right coronary catheter was positioned in the descending aorta below the renal arteries to monitor blood pressure. One quadripolar catheter (interelectrode distance of 1 cm) was positioned across the tricuspid valve to record the His bundle electrogram and another quadripolar catheter (interelectrode distance of 1 cm) was used to pace and record from the high right atrium and the right ventricle. Surface electrocardiographic leads I, III and V_1 together with 2 intracardiac electrograms (filtered at 50 to 300 Hz) were recorded on magnetic tape and reproduced on a multichannel recorder (Hewlett-Packard 1308A) at a paper speed of 100 mm/s. Pacing was performed using a Medtronic 5325 programmable stimulator delivering rectangular pulses 2 ms in duration. No patient was taking antiarrhythmic or β-blocking drugs at the time of the study.

Programmed ventricular stimulation was performed in a preestablished sequence to an end point of 10 or more induced consecutive intraventricular reentrant beats. This response was considered to represent ventricular electrical instablity. The programmed ventricular stimulation sequence was: ventricular pacing at 2 cycle lengths (S_1S_1—600 ms and 462 ms) with single extrastimulus (S_2) from the right ventricular apex at 2 mA; ventricular pacing at the same cycle lengths with double extrastimuli (S_2S_3) from the right ventricular apex at 2 mA. If the end point was not reached, sequences 1 and 2 were repeated at a stimulus intensity of 10 mA. Then the catheter was moved to the right ventricular outflow and sequences 1 and 2 repeated at 2 mA and 10 mA. Sustained VT was defined as VT that caused hemodynamic compromise which required pacing or cardioversion for immediate termination or if stable lasting for at least 30 seconds. Nonsustained VT was defined as VT that lasted less than 30 seconds. No complications related to the study were observed.

Follow-up: All patients were followed up at regular intervals up to 16 months (338 ± 99 days, range 128 to 483) by telephone or in the clinic. The results of programmed ventricular stimulation did not influence subsequent management except in 3 patients who had both spontaneous and induced sustained VT. When clinically indicated, complex ventricular arrhythmias were treated with amiodarone.

Statistical analysis: Statistical analysis was performed by using χ^2 and the Student t test for unpaired data. All values given in the text represent mean ± standard deviation of the mean. Differences were considered significant when $p < 0.05$.

Results

Clinical characteristics: The clinical characteristics of the study group are presented in Table I. Seventeen patients had an anterior, 30 an inferior and 3 a nontransmural AMI. Two patients had prior AMI. Eighteen patients were in Killip class II on admission and 32 patients in Killip class I. Maximal CK (IU/liter) was 1,304 ± 845. Sustained VT or ventricular fibrillation (VF) occurred in the coronary care unit in 4 patients, while 3 patients presented with sustained VT in the late phase (11, 17 and 18 days after admission). Complex ventricular arrhythmias (Lown class III or higher) were observed in 24 patients and episodes of nonsustained VT (3 or more consecutive premature ventricular beats) were documented in 6 (Table I).

Angiographic findings: One-vessel disease was present in 21 patients, 2-vessel disease in 16 and 3-vessel disease in 12, and 1 patient had no significant coronary artery narrowing. The mean ejection fraction was 0.45 ± 0.10, and 20 patients had an ejection fraction less than 0.40. The mean left ventricular end-diastolic pressure was 14.7 ± 5 mm Hg and more than 20 mm Hg in 9 patients. Severe wall motion abnormalities were observed in 34 patients.

Electrophysiologic findings: Twenty patients had 0 to 4 beats at intraventricular reentry, 7 patients 5 to 9, 5 patients 10 to 20, and 8 patients more than 20. Ten

TABLE II Mode of Induction of Intraventricular Reentrant Beats in the Group with Ventricular Electrical Instability

	RVA		RVO	
	S_1S_2	$S_1S_2S_3$	S_1S_2	$S_1S_2S_3$
2 mA	2	10	0	3
10 mA	0	5	0	3

VEI = ventricular electrical instability; RVA = right ventricular apex; RVO = right ventricular outflow tract.

patients had sustained VT induced. Twenty-three patients (46%) had 10 or more (ventricular electrical instability group) and 27 (54%) had 10 or less beats induced. Of the 23 patients with ventricular electrical instability, 10 had sustained and 13 had nonsustained VT. In the sustained VT group, 7 patients showed monomorphic tachycardia (cycle length 268 ± 72 ms): 5 with left bundle branch block and 2 with right bundle branch block morphology; and 3 patients had polymorphic VT induced (cycle length 186 ± 15 ms). In the nonsustained VT group, 5 patients had monomorphic VT induced (cycle length 212 ± 13 ms): 4 with left bundle branch block and 1 with right bundle branch block morphology; and 8 patients had polymorphic VT induced (cycle 200 ± 35 ms).

The mode of induction of the intraventricular reentry in the 23 patients with ventricular electrical instability is listed in Table II. In 17 patients, intraventricular reentry was induced from the right ventricular apex, using single extrastimulus in 2 and double in 15; intraventricular reentry was induced at 2 mA in 12 and at 10 mA in 5. In 6 patients intraventricular reentry was induced from the right ventricular outflow, using double extrastimuli at 2 mA in 3 and at 10 mA in 3.

Of the 10 episodes of sustained VT, 5 were terminated by short bursts of ventricular pacing and 5 required cardioversion for rapid hemodynamic deterioration.

Comparison between groups with and without ventricular electrical instability: Twenty-three patients (46%) had 10 or more intraventricular reentrant beats induced (ventricular electrical instability group) and 27 (54%) had 10 or less consecutive beats (group without ventricular electrical instability) initiated with programmed ventricular stimulation. No significant differences were observed in age, site of myocardial infarction, maximal CK and occurrence of spontaneous sustained VT or VF (early or late). All 3 patients who had spontaneous sustained VT in the late hospital phase had their clinical VT induced (Table I).

Holter monitoring showed that 16 patients (69%) in the ventricular electrical instability group had Lown class 3 or higher arrhythmia compared with 8 patients (29%) in the group without ventricular electrical instability ($\chi^2 = 6.42$, $p = <0.01$). Five patients (21%) in the group with and 1 (3%) in the group without ventricular electrical instability had nonsustained VT (Lown class 4B) ($\chi^2 = 2.31$, difference not significant [NS]).

No significant differences were found between the group with and the group without ventricular electrical instability with respect to ejection fraction (0.42 ± 0.7 vs 0.47 ± 0.12), prevalence of 1-vessel (43% vs 41%), 2-vessel (35% vs 30%) and 3-vessel disease (22% vs 26%). One patient (3%) in the group without ventricular electrical instability had no angiographic coronary disease. The mean left ventricular end-diastolic pressure was 15 ± 4 mm Hg in the ventricular electrical instability group and 14 ± 5 mm Hg in the group without ventricular electrical instability (NS). Five patients (18%) in the group with and 4 (15%) in the group without ventricular electrical instability had a left ventricular end-diastolic pressure greater than 20 mm Hg (NS). Severe wall motion abnormalities (1 or more akinetic or dyskinetic segments) were found in 18 patients (78%) in the group with in 16 (59%) in the group without ventricular electrical instability (NS).

TABLE III Therapy and Holter Monitoring Data in Patients With and Without Ventricular Electrical Instability During Follow-Up

	VEI (23 pts)	No VEI (27 pts)	p
Amiodarone (275 ± 103 mg/day)	8 (34%)	4 (14%)	NS
β-blocking drugs	4 (17%)	4 (14%)	NS
CABG	2 (8%)	5 (19%)	NS
Lown class >3	13 (76%)	12 (60%)	NS
Lown class 4B	6 (35%)	0 (0%)	<0.01

* Holter monitoring data were available in 17 patients in the group with and 20 patients in the group without ventricular electrical instability.

CABG = coronary artery bypass graft; NS = not significant; VEI = ventricular electrical instability.

Follow-up data: The discharge medications are listed in Table III. No significant treatment differences were observed between the 2 groups (amiodarone 34% vs 14%, β-blocking drugs 17% vs 14%, and coronary artery bypass surgery 8% vs 19%).

Thirty-seven patients had at least one 24-hour Holter recording during follow-up (17 in the group with and 20 in the group without ventricular electrical instability) (Table III). Lown class 3 or higher ventricular arrhythmias were present in 76% of the group with and in 60% of the group without ventricular electrical instability ($\chi^2 = 1.3$, NS). Nonsustained VT was observed in 35% of the patients in the group with and in none of the patients in the group without ventricular electrical instability ($\chi^2 = 8.7$, $p = <0.01$). During a mean follow-up of 11.2 months, 1 patient died from sepsis in the group with ventricular electrical instability, after coronary artery surgery. There were no sudden deaths in either group.

Discussion

We prospectively evaluated the clinical significance of intraventricular reentry induced by programmed ventricular stimulation in 50 consecutive, hemodynamically stable patients, who had survived the acute phase of myocardial infarction. Our major findings were: (1) programmed ventricular stimulation, performed 17 to 40 days (mean 25) after myocardial infarction, showed a high prevalence of ventricular electrical instability (46%) and, (2) ventricular electrical instability

did not correlate with hemodynamic and angiographic data.

Green et al,[1] using a PVS protocol, including a single ventricular extrastimulus during atrial pacing, induced intraventricular reentry (1 or more ventricular premature beats) in 19 (39%) of the 48 patients after AMI. Hamer et al,[2] using a more aggressive protocol (double ventricular extrastimuli at 2 right ventricular sites, and a stimulus intensity of 2 V and 10 V, studied 70 patients 7 to 20 days (mean 11) after AMI. Ventricular electrical instability, defined as more than 5 consecutive premature ventricular beats, was observed in 12 patients (17%). Richards et al,[3] using a similar programmed ventricular stimulation protocol (double ventricular extrastimuli at 2 right ventricular sites, and stimulus intensity of twice diastolic threshold and 20 mA) studied 165 patients 6 to 28 days (mean 10) after AMI. Ventricular electrical instability, defined as induction of VF or VT lasting at least 10 seconds, was found in 38 patients (23%). Marchlinski et al,[5] using single and double ventricular extrastimuli from the right ventricular apex, studied 46 patients 8 to 60 days (mean 22) after AMI. Ventricular electrical instability, defined as sustained VT or nonsustained VT (4 or more beats), was observed in 8 patients (18%). Borggrefe et al,[6] using single and double ventricular extrastimuli during sinus rhythm and several ventricular paced cycle lengths, studied 203 patients up to 60 months after AMI. Ventricular electrical instability, defined as 4 or more ventricular echo beats, was found in 20% of those studied 1 month or less after the infarct.

In our study, using a programmed ventricular stimulation protocol similar to that used by Hamer et al[2] and Richards et al,[3] the prevalence of ventricular electrical instability, defined as the induction of 10 or more intraventricular reentrant beats, was 46% (higher than previously reported).

Green et al[1] found that 79% of patients with ventricular electrical instability had symptomatic VT or sudden death, or both, compared with 14% of these who did not have repetitive ventricular responses ($p < 0.001$). Hamer et al[2] found that patients with ventricular electrical instability had a significantly higher incidence of sudden death compared with patients without ventricular electrical instability ($p < 0.05$). Richards et al[3] found that ventricular electrical instability assessed by programmed ventricular stimulation was predictive of the development of spontaneous VT or sudden death during a mean follow-up of 8 months ($p < 0.001$). In a subsequent report, Holley et al,[7] from the same laboratory, showed that induction of VF in these patients was not associated with sudden death during follow-up. Marchlinski et al[5] and Borggrefe et al[6] failed to observe any correlation between ventricular electrical instability and sudden death, although in the study of Borggrefe, ventricular electrical instability was associated with subsequent development of sustained VT.

Although we found a high prevalence of ventricular electrical instability, no sudden death was observed during follow-up. The stable clinical condition (Killip class II or less) of our patients may account for the low mortality during follow-up. The absence of sudden death may be partially explained by aggressive treatment of 3 patients with spontaneous, symptomatic sustained VT: 1 had aneurysmectomy for intractable VT and 2 underwent serial electrophysiologic studies for selection of an antiarrhythmic drug regimen. Furthermore, 18% of our patients received antiarrhythmic drugs on an empiric basis. Although empiric antiarrhythmic therapy has not been demonstrated to reduce cardiac mortality after myocardial infarction, this possibility, using amiodarone, can not be completely ruled out in our study.

We conclude that in patients who are hemodynamically stable after acute myocardial infarction, (1) programmed ventricular stimulation can be safely performed; (2) there is a high prevalence of inducible sustained and nonsustained VT, which does not correlate with the clinical or angiographic data; (3) after discharge, those with ventricular electrical instability show a higher incidence of nonsustained VT during Holter monitoring than those without ventricular electrical instability; and (4) the predictive value of programmed ventricular stimulation in sudden death can not be addressed by our study because of low incidence of fatal events and high prevalence of therapy.

Bretylium: Relations Between Plasma Concentrations and Pharmacologic Actions in High-Frequency Ventricular Arrhythmias

HENRY J. DUFF, MD, DAN M. RODEN, MD, AVRAHAM YACOBI, PhD, DAVID ROBERTSON, MD, THEODORE WANG, MD, REBECCA J. MAFFUCCI, RN, JOHN A. OATES, MD, and RAYMOND L. WOOSLEY, MD, PhD

Although it is widely assumed that the early arrhythmogenic and pressor responses to bretylium are caused by catecholamine release from the adrenergic neuron, this assumption has not been systematically studied in humans. Pharmacologic responses to a placebo infusion and 3 separate bretylium infusions (2.5, 5.0, 10 mg/kg over 60 minutes) were assessed in 6 patients with recurrent, nonsustained ventricular tachycardia. Plasma bretylium concentration, blood pressure (BP), plasma norepinephrine (NE) concentration, arrhythmia frequency and adrenergic neuronal blockade (assessed by the presence or absence of reflex venoconstriction) were measured. Adrenergic blockade was seen with every bretylium infusion and at a time when relatively small amounts of bretylium had been administered (range 160 to 750 mg, median 252). Temporal relations ($p < 0.03$) were noted among the time of onset of adrenergic neuronal blockade, onset of the pressor response, increase in NE plasma concentration and increase in ventricular arrhythmia frequency. BP responses during the infusions were linearly related to change in plasma NE at the time of development of adrenergic neuronal blockade. Bretylium plasma concentrations higher than 3 μg/ml were frequently associated with a short-lived pressor response. There was a significant relation ($p < 0.06$) between the increase in plasma NE during the infusion and an increase in ventricular arrhythmia frequency. Reduction in arrhythmia frequency was seen in only 1 patient, beginning 6 hours after the development of adrenergic neuronal blockade. In conclusion, soon after bretylium administration to patients with ventricular arrhythmias, a dose-related increase in BP and arrhythmia frequency occurred that were temporally related to catecholamine release and adrenergic neuronal blockade. Lack of antiarrhythmic response in this highly selected population does not detract from the proved efficacy of bretylium in patients with recurrent sustained ventricular tachycardia and fibrillation.

Bretylium, a quarternary ammonium compound, is effective in the treatment of life-threatening ventricular arrhythmias in humans.[1–5] Its widespread use has been limited by complex pharmacodynamic features,[6–11] including a short-lived initial "sympathomimetic" phase (associated with sinus tachycardia, positive inotropic effects[8,11] and local release of norepinephrine (NE) from adrenergic terminals in the heart[11] of dogs) followed by prolonged orthostatic hypotension due to adrenergic neuronal blockade.[8] Case reports indicate that the initial sympathomimetic phase is, at times, associated with

increase in ventricular arrhythmia frequency.[12,13] Although the early arrhythmogenic and pressor effects of bretylium are believed to be caused by catecholamine release, this had not been systematically evaluated in man. In this study 6 patients with high-frequency ventricular arrhythmias received 4 separate infusions in a randomized sequence; placebo and bretylium infusions of 2.5, 5 and 10 mg/kg. The relations among changes in ventricular arrhythmia frequency, plasma bretylium and NE concentrations, blood pressure (BP), electrocardiographic intervals and the presence or absence of adrenergic neuronal blockade were assessed.

Methods

Study design: Patients whose high-frequency ventricular arrhythmias were stable during prolonged recumbency and with no known reversible causes were candidates for this study. Patients with angina, congestive heart failure (New York Heart Association class III or IV), aortic stenosis, abnormal renal disease (creatinine clearance less than 60 ml/min), abnormal liver function or unstable concurrent illnesses were excluded. This study was approved by the Committee for the Protection of Human Subjects of Vanderbilt University and all patients gave informed consent. At least 4 half-lives after withdrawal of all medications, the frequency of ventricular premature complexes (VPCs) was determined during 3 hours of supine rest. If the supine arrhythmia frequency was greater than 120 VPCs/hour throughout this period, the patient was admitted to the study. All patients were maintained on a 2-g-sodium, caffeine-free diet.

Each patient received 4 separate infusions of placebo and bretylium (2.5, 5 and 10 mg/kg, supplied by American Critical Care) in a randomized sequence. The infusions were separated from each other by at least 48 hours and subsequent infusions were only given if both BP (standing and supine) and arrhythmia frequency had returned to baseline levels. To minimize the chance of a carryover effect, the randomization sequence did not permit the 10-mg/kg infusion to precede a 2.5-mg/kg or placebo infusion. Individual studies consisted of a 30-minute control period followed by a 30-minute placebo infusion (5% dextrose), followed by the 1-hour treatment infusion (placebo or bretylium). The infusions were administered with a Harvard model 600 pump. Clinical observations were made every 15 minutes during the control and dextrose infusion periods and every 5 to 15 minutes during treatments. These measurements included BP and pulse (both supine and 35° tilt), ventricular arrhythmia frequency, electrocardiographic intervals, plasma bretylium concentration, plasma NE concentration and the presence or absence of reflex venoconstriction (venous reflex response), described later. The PR, QRS, QT and RR intervals were measured after at least 5 consecutive sinus beats; rate corrected QT (QTc) was calculated from the formula $QTc = QT/\sqrt{RR}$. After the treatment periods, electrocardiographic data were continuously recorded for 48 hours.

Arrhythmia frequency: Electrocardiograms were recorded from a telemetry signal on a Honeywell model 96, FM, 8-channel recorder. The taped data were then analyzed by a computer operator, who was blinded to the treatment being given, using a PDP 11/60 minicomputer and a previously described and verified template-matching program.[14] This system quantifies the number of VPCs, ventricular couplets and runs of ventricular tachycardia (VT) (more than 3 consecutive VPCs at a cycle length shorter than 600 ms).

The change in arrhythmia frequency during bretylium infusions was established by a comparison to the arrhythmia frequency seen during the 1-hour placebo infusion. Late antiarrhythmic and electrocardiographic changes were sought by comparing electrocardiographic data during the first 6 and second 6 hours after the bretylium infusions to the corresponding hours after placebo infusion.

Pharmacokinetic assessment: Plasma samples for analysis of bretylium concentration and vital signs (BP and pulse, supine and sitting) were obtained at 0, 0.25, 0.5, 0.75, 1.0, 1.5, 2.0, 2.5, 3, 4, 5, 6, 8, 10, 12, 18, 24, 36 and 48 hours after beginning the bretylium infusions. The plasma concentrations were fitted to a 2-compartment open model incorporating a 1-hour infusion period, using the program NONLIN. The negative slope (elimination constant, Kel) was calculated from the best fit for the terminal portion of the time-log concentration plot. The area under the curve (AUC) was calculated by the trapezoidal rule with extrapolation to infinity. Systemic clearance was calculated using the formula: clearance = dose/AUC. A gas-liquid chromatographic system was used to quantify bretylium concentrations in plasma.[15] Plasma NE concentrations in plasma were quantified using a radioenzymatic assay.[16]

Venous reflex response: A 19-gauge intravenous cannula was introduced into a superficial vein on the dorsum of the hand and connected to a calibrated pressure transducer. A pediatric BP cuff was placed at the wrist and inflated to 300 mg Hg. This effectively isolates the hand from the circulation, yet leaves the vein capable of responding to neural stimuli.[17,18] The stimulus used to elicit reflex venoconstriction in this study was a deep breath.[19] Loss of the venous reflex response has been documented with the use of adrenergic blocking drugs such as guanethidine. The presence or absence of reflex venoconstriction was assessed at least once during the control period, once during the dextrose infusion and every 5 to 15 minutes during treatment.

Results

Six men, aged 42 to 64 years (mean 54), participated in this study: 2 with hypertensive heart disease, 2 with ischemic heart disease and the 2 with no known structural heart disease. Twenty-two other patients were considered but were excluded because of marked time-dependent decrease in ventricular arrhythmia frequency during recumbency. None of the 6 selected patients received medications other than bretylium or placebo during this study. All patients had short bursts of self-limited VT during ambulatory monitoring that were resistant to conventional antiarrhythmic agents. Group mean arrhythmia frequency during the control dextrose infusion was 558 ± 223 VPCs/hour (± standard deviation), with 37 ± 29 couplets and 0.4 ± 0.3 episodes of VT per hour. A similar arrhythmia frequency was seen during the subsequent 1-hour placebo infusion (339 ± 145 VPCs with 27 ± 22 couplets and 0.4 ± 0.3 episodes of VT), indicating the relative stability of arrhythmia frequency during this time.

Adrenergic neuronal blockade: The overall pharmacodynamic features are presented in Figure 1. Adrenergic neuronal blockade developed in all patients during bretylium infusions, but at 62 ± 12 minutes with the 2.5-mg/kg dose; 33 ± 4 minutes with the 5.0-mg/kg dose; and 35 ± 15 minutes with 10/mg/kg infusion. Figure 2 shows the cumulative proportion of subjects who lost the venous reflex response (development of adrenergic neuronal blockade) in relation to the dosage of bretylium administered at that time.

Pressor response: Figure 1 illustrates plasma concentrations of bretylium relative to changes occurring in BP. There was a nonsignificant decrease in BP with the 2.5-mg/kg infusion. In contrast, the 10-mg/kg infusion of bretylium resulted in higher concentrations of bretylium and a significant pressor response ($p < 0.05$). Low-dose bretylium infusion was associated with a reduction in plasma NE, while high-dose infusion resulted in increase in plasma NE and an associated pressor response. Figure 3 illustrates the strong temporal relation among the onset of the pressor response, NE release and adrenergic neuronal blockade. A linear relation was also noted between bretylium concentration at time of loss of the venous reflex response and the extent of subsequent change in BP ($r = 0.65$, $p < 0.01$). Subjects with plasma bretylium concentrations greater than 3 μg/ml at the time of loss of venous reflex response generally had a pressor response. A relation was also noted between maximal change in BP during the

bretylium infusion and maximal change in NE concentration occurring over the same period (Fig. 4) ($r = 0.82$, $p < 0.01$)].

Arrhythmia frequency: The 2.5-mg/kg bretylium infusion was not associated with a change in arrhythmia frequency, while the 10 mg/kg infusion resulted in a short-lived significant increase in frequency of PVCs, ventricular couplets and VT. Table I illustrates the significant relation ($p < 0.06$) between presence or absence of increase in plasma NE (>50 pg/ml above the control) during the infusion to presence or absence of worsening of ventricular arrhythmias (defined as a 100% or greater increase in VPC frequency relative to control, paralleled by an increase in ventricular couplets or by the onset of episodes of VT not seen during control observations). Although there is an association between these variables, several subjects had discordant results; worsening of ventricular arrhythmias did occur in the absence of measurable increases in plasma NE in 4 of 17 infusions.

The only patient who had frequent episodes of VT was also the only patient who had an antiarrhythmic response to bretylium, beginning 6 hours after the bretylium infusion was stopped. This delayed antiarrhythmic effect coincided temporally with development of electrocardiographic interval changes.

Electrocardiographic interval changes: No changes were seen in QRS duration and QTc during or after bretylium infusions in any of the patients. However, during the early sympathomimetic period (10-mg/kg infusions), shortening of the sinus cycle length (i.e., increased heart rate) was associated with shortening of the coupling interval of the predominant ventricular premature template (Fig. 5A). Also, beginning 6 hours after stopping the bretylium infusion, prolongation of the coupling interval of the predominant ventricular premature template was seen (Fig. 5B).

Pharmacokinetic parameters: A nonlinear relationship was noted between administered dose and resultant area under the plasma concentration curve, and clearance appears to increase with dose (Table II). No significant dose-dependent changes in Kel were noted. Peak plasma concentrations during the 2.5, 5.0 and 10 mg/kg infusions were 1.8 ± 4.5, 3.2 ± 0.8 and 5.0

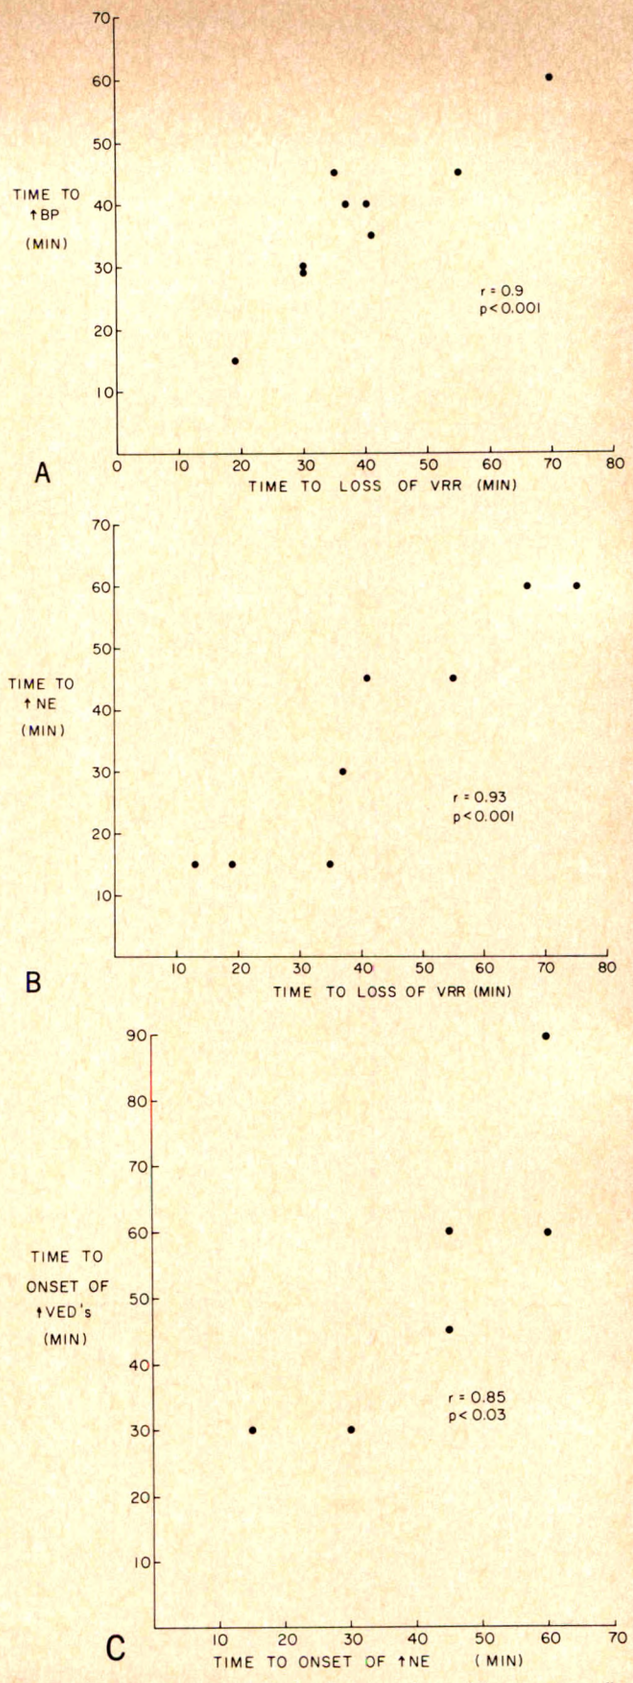

FIGURE 3. The temporal relation between loss of the venous reflex response (VRR) and (**A**) the onset of a pressor response, (**B**) onset of norepinephrine (NE) release, and (**C**) temporal relation between onset of arrhythmia worsening and onset of norepinephrine release. BP = blood pressure; VED = ventricular ectopic depolarization.

± 3.6 μg/ml (mean ± standard deviation), respectively.

Side effects: Nausea occurred in 3 patients, all during the 10 mg/kg infusion and at a mean plasma concentration of 5.3 ± 0.9 μg/ml. All patients had orthostatic hypotension after the bretylium infusions.

Discussion

Data from animal models suggest that bretylium is taken up by the amine pump in the adrenergic neuron and blocks subsequent release of catecholamines mediated by neuronal discharge.[8,20] In this study in man, adrenergic neuronal blockade occurred after relatively small dosages of bretylium—doses less than those generally required to suppress ventricular arrhythmias under clinical conditions. These findings are in agreement with other experimental and clinical data, suggesting that the antiarrhythmic actions of bretylium are independent of neuronal blockade.[1,21–23] Evidence for direct antiarrhythmic effects include the absence of antifibrillatory effects seen with sympatholytic interventions such as catecholamine depletion with reserpine or adrenergic blockade with quanethidine; continued clinical antiarrhythmic effects of bretylium when adrenergic neuronal blockade is reversed by the addition of a tricyclic antidepressant[24]; and the delayed onset of antiarrhythmic effect[4] well after the development of adrenergic neuronal blockade. In keeping with this concept, the only subject in this study who had an antiarrhythmic response had it 6 hours after the development of adrenergic neuronal blockade. The delayed onset of this antiarrhythmic effect may parallel a delayed myocardial accumulation of bretylium, which has been reported to peak 3 to 12 hours after acute administration.[25] We also noted a similar delayed electrocardiographic effect, consisting of an increase in the coupling interval of the predominant ectopic focus, which may be a marker of bretylium's direct myocardial effect.

Animal studies indicate that bretylium initially causes a displacement of catecholamines from the terminal storage vesicles of the adrenergic neuron[8–11] and that the extent of release appears to be dose-dependent.[26] This study supports the concept that this same construct also applies in man. Pressor effects often occurred when plasma bretylium concentrations were greater than 3 μg/ml and the extent of change in BP was linearly related to change in plasma NE. The strong temporal relations among onset of the pressor response, NE release and adrenergic neuronal blockade also supports the concept of catecholamine displacement.

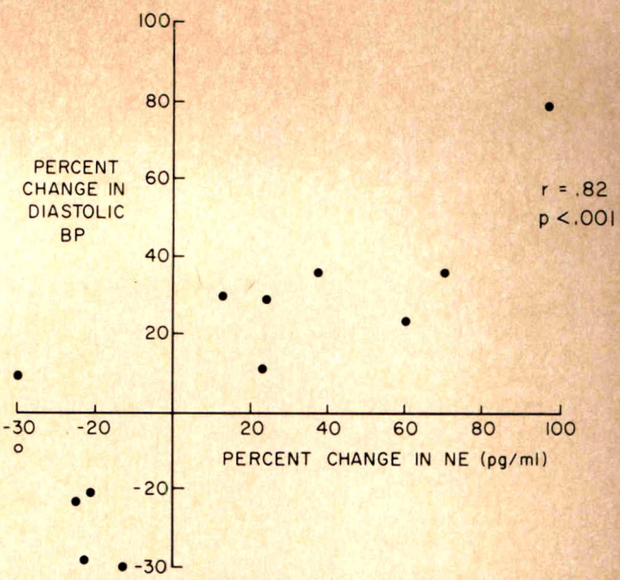

FIGURE 4. Linear relation between maximal changes in blood pressure (BP) and norepinephrine (NE) concentration during bretylium infusion.

Because of the sporadic nature of ventricular arrhythmias, the initial worsening of arrhythmia frequency was established by several criteria. First, a dose-response relation was seen during the administration of increasing dosages. Second, the increase in ventricular ectopic depolarizations was generally paralleled by an increase in frequency of ventricular couplets and episodes of nonsustained VT. Third, during placebo infusions (over the same time period), worsening of ventricular arrhythmias were not observed. Although isolated case reports have suggested that bretylium could precipitate the development of sustained VT during its early sympathomimetic phase,[13]

in this study episodes of VT were limited to 5-beat salvos in 1 patient and only triplets occurred in the other patients.

While substantial evidence exists for the efficacy of bretylium in the treatment of resistant VT or ventricular fibrillation, bretylium has not been convincingly effective in the treatment of high-frequency chronic ventricular arrhythmias. In the study by Romhilt et al,[27] 5 of 8 patients had a 50% or greater suppression of ventricular ectopic beats over placebo on 24-hour recordings. However, an 83% reduction in VPCs is required to distinguish a true antiarrhythmic response from spontaneous variability.[28] In the present study, no antiarrhythmic response was seen either early or late in 5 of the 6 patients. Bretylium's lack of ability to suppress VPCs may relate to its electrophysiologic actions. Unlike many other antiarrhythmic agents, bretylium does not affect conduction velocity, increase the ratio of ventricular effective refractory period to action potential duration or depress automaticity.[29,30] Bretylium's antiarrhythmic and antifibrillatory effects may relate to its ability to reverse maintenance factors that allow arrhythmias to become sustained (dispersion of repolarization between ischemic and normal ventricular tissue[30]). While this pharmacologic effect may suppress VT and ventricular fibrillation, it may not suppress simple VPCs.

In conclusion, bretylium produces a dose-related increase in BP and arrhythmia frequency that is short-lived and is temporally related to cathecholamine release and adrenergic neuronal blockade.

Continuous Electrical Activity During Sustained Monomorphic Ventricular Tachycardia

Observations on Its Dynamic Behavior During the Arrhythmia

PEDRO BRUGADA, MD, HOSHIAR ABDOLLAH, MD, and HEIN J. J. WELLENS, MD

Catheter mapping was performed during sinus rhythm and monomorphic ventricular tachycardia (VT) in 56 consecutive patients with sustained, monomorphic VT. Forty-two patients had an old myocardial infarction (VT-old MI group), 6 patients had right ventricular dysplasia (VT-RV dysplasia group), and 8 patients had idiopathic VT (idiopathic-VT group). Continuous electrical activity was recorded in 15 of 42 patients of the VT-old MI group (36%), 5 of 6 of the VT-RV dysplasia group (83%), and in 0 of 8 patients in the idiopathic VT group (0%). In 17 of 20 patients with continuous electrical activity during VT, observations on the dynamic behavior of continuous electrical activity during VT revealed at least 1 of the following characteristics: (1) spontaneous disappearance and reappearance of continuous electrical activity without changes in rate, morphologic pattern or axis of VT; (2) pacing-induced transient termination of continuous electrical activity without termination of VT; (3) spontaneous disappearance of continuous electrical activity during VT as a rate-dependent phenomenon; (4) Wenckebach-like conduction to other areas resulting in transient and periodic continuous electrical activity; (5) dependence of continuous electrical activity on ventricular activation pattern during VT; (6) pacing-induced change from a noncontinuous electrogram into continuous electrical activity without prevention of termination of VT; and (7) termination of continuous electrical activity after antiarrhythmic drugs without termination of VT. Continuous electrical activity was always recorded in the aneurysm and never over normal heart areas. At the sites where continuous electrical activity was recorded during VT, potentials recorded during sinus rhythm were abnormal. Our observations suggest that several electrophysiologic phenomena can simulate continuous electrical activity during monomorphic VT. Transient, continuous electrical activity is a frequent phenomenon that represents electrical activity from abnormal areas not necessarily required to perpetuate VT.

(Am J Cardiol 1985;55:402–411)

Since the early studies on experimental atrial flutter by Sir Thomas Lewis,[1] mapping of electrical activity of the heart has been extensively used in the experimental and clinical laboratory. Several investigators, using mapping techniques, have demonstrated the reentrant nature of a variety of arrhythmias.[2–7] Application of the information from experimental studies to the clinical situation has resulted in the development of new surgical techniques for treatment of patients with arrhythmias.[8–13] However, the interpretation of the results of clinical mapping still remains difficult. Long-lasting electrical activity is expected to be registered when recording is done directly from a reentrant circuit. It has been questioned, however, that the recording of electrical activity spanning the cardiac cycle (continuous electrical activity) always proves that the catheter is located at the site of the reentry circuit.[7,14,15] Continuous electrical activity has not been clearly defined qualitatively or quantitatively. To investigate the incidence and significance of electrical activity spanning the cardiac cycle during catheter mapping of monomorphic ventricular tachycardia (VT), a prospective study was undertaken in 56 patients. In these patients the dynamic behavior of endocardial electrical activity during VT was studied.

Methods

Fifty-six consecutive patients with clinically documented, sustained, monomorphic VT were studied. Their clinical data are given in Table I. Forty-two patients had an acute myocardial infarction (MI) 3 weeks to 13 years before study (VT-old MI group). Their first episode of VT developed 6 days to 6 years after MI. Six patients had the syndrome of right ventricular (RV) dysplasia (VT-RV dysplasia group). In 8 patients no abnormalities were found to explain the cause of their VT (idiopathic-VT group). No patient with ventricular fibrillation or polymorphic VT, was included in the study.

Each patient gave informed consent. The 56 patients then underwent an electrophysiologic investigation using previously described methods of stimulation, recording and analysis of tracings.[16] All antiarrhythmic drugs were stopped at least 72 hours before study. After the mode of initiation and termination of VT was assessed, mapping of right and left ventricular endocardial activation was performed during sinus rhythm. Eight to 20 right and left ventricular sites were mapped. The catheter used was a quadripolar electrode (Josephson catheter, USCI) with an interelectrode distance of 0.5 cm. Recordings were made from electrodes 1 to 3 and

TABLE I Clinical Data on 56 Patients

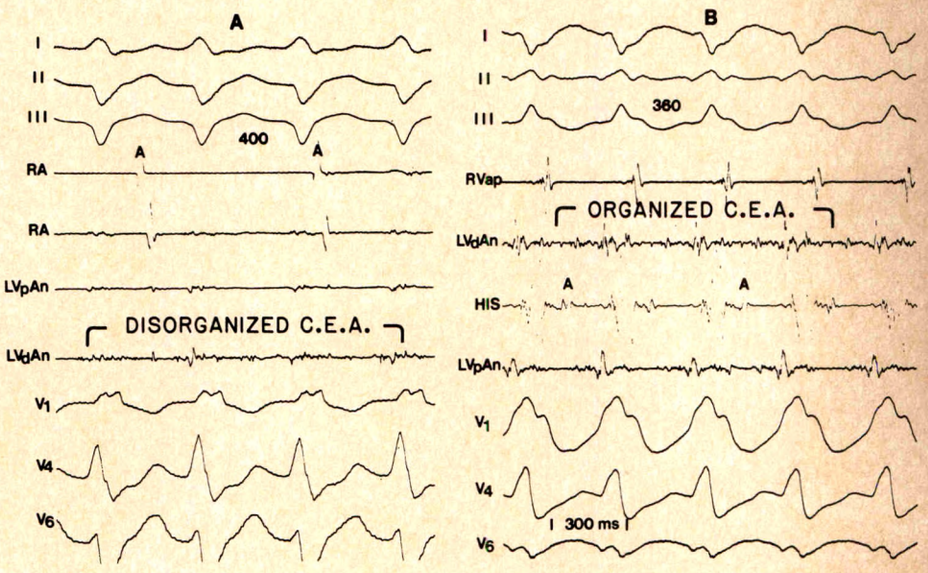

FIGURE 1. The 2 types of continuous electrical activity (C.E.A.) observed during ventricular tachycardia. **A,** disorganized continuous electrical activity in the distal left ventricular recording from the aneurysm (LV_dAn). **B,** regular repetitive pattern of continuous electrical activity (organized continuous electrical activity) in the LV_dAn. Six surface leads are simultaneously shown, with bipolar electrograms from the right atrium (RA), right ventricular apex (RVap), His bundle and proximal (p) and distal (d) LVAn.

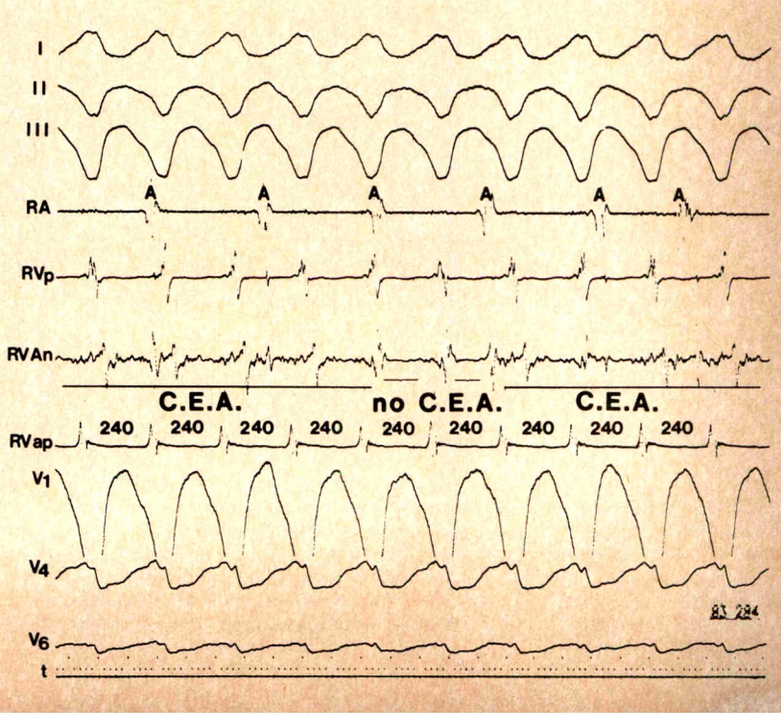

FIGURE 2. Spontaneous disappearance and reappearance of continuous electrical activity (C.E.A.) during ventricular tachycardia (VT) without changes in rate or morphologic pattern of VT in a patient with right ventricular (RV) dysplasia. In the **left** and **right** part of the figure, continuous electrical activity is recorded in the bipolar recording from an RV aneurysm (RVAn). In the **middle** part of this tracing, continuous electrical activity disappears, without changes in VT. Six surface leads are shown simultaneously recorded with bipolar electrograms from the right atrium (RA), proximal right ventricle (RVp), RV aneurysm (RV An) and RV apex (RVap).

2 to 4 in order to obtain 2 bipolar electrograms (1-cm interelectrode distance) which were separated 0.5 cm from each other. In patients with localized wall motion abnormalities, mapping was always started over the normal heart areas. Thereafter, mapping was performed inside the aneurysm. When abnormal potentials (<1 mV, duration >50 ms, or occurring after the end of the QRS complex in the surface leads) were present during sinus rhythm the catheter, was positioned at this site and in this position VT initiated. The effect of timed ventricular premature beats and overdrive ventricular pacing on the abnormal potentials during VT was then studied. The same procedure was repeated at other ventricular sites. This was also done during intravenous administration of an antiarrhythmic agent, when possible. The catheter position and stability were frequently controlled by biplane fluoroscopy. All recorded electrograms were filtered between 40 and 500 Hz. The gain was adjusted as low as possible, with a maximum at 1 mV = 3 cm.

Continuous electrical activity was defined as the presence of electrical activity bridging 2 consecutive QRS complexes during VT. Double potentials during VT clearly separated by an isoelectric line were not considered to represent continuous electrical activity, but continuous electrical activity was diagnosed in 1 patient showing 3 potentials separated by an isoelectric line during 1 VT cycle.

Results

Incidence and types of continuous electrical activity: Diastolic activity after the QRS complex but not completely bridging the distance between 2 consecutive QRS complexes was observed during VT in all 42 patients in the VT-old MI group, all 6 patients in the VT-RV dysplasia group, and in none of the 8 patients of the idiopathic VT group. Continuous electrical activity during monomorphic VT was recorded in the left ventricle in 15 patients (36%) from the VT-old MI group, in 5 (83%) from the right ventricle in the RV

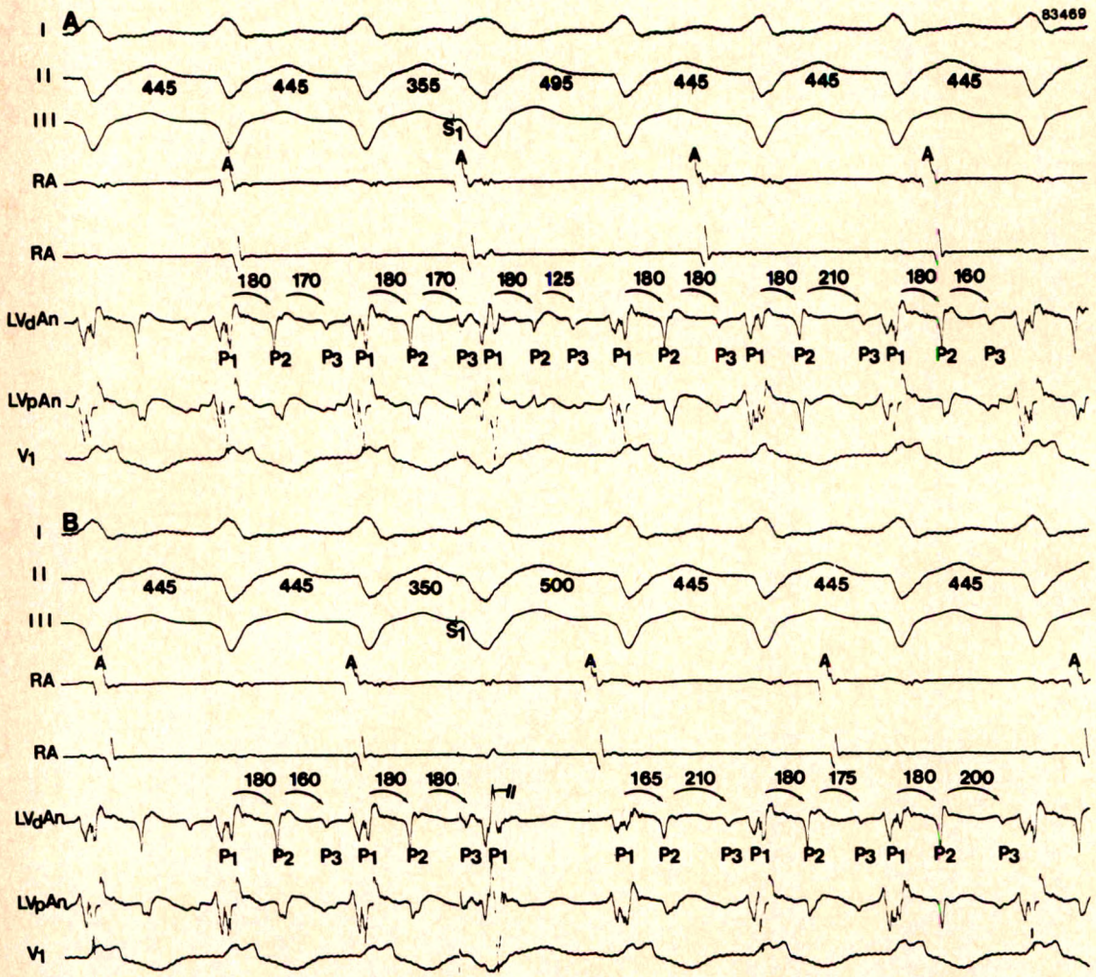

FIGURE 3. The effect of a single ventricular premature beat (S_1) on continuous electrical activity during ventricular tachycardia (VT). Three potentials (P_1, P_2 and P_3) are present on the distal left ventricular recording from the aneurysm (LV_dAn) during VT. **A,** an S_1 given after 355 ms does not terminate VT, but clearly changes the intervals between P_1, P_2 and P_3. Alternation in the P_2-P_3 interval from 160 to 210 ms is thereafter observed. This does not influence the cycle length or morphologic pattern of VT. **B,** an S_1 given 5 ms earlier than that in panel **A** (350 ms) does not terminate tachycardia, but P_1 is not followed by P_2 or P_3. These potentials reappear in the next VT cycles, again showing alternation in the P_2-P_3 interval. The P_1-P_2 interval is shorter after the pause produced by S_1. From these observations one may conclude that P_2 and P_3 are not an essential link in the VT circuit. Four surface leads are shown that were recorded simultaneously with 2 bipolar electrograms from the right atrium (RA) and the left ventricular aneurysm (LVAn). P = proximal.

dysplasia group and in no patient from the idiopathic-VT group.

Two types of continuous electrical activity were identified. Disorganized continuous electrical activity was characterized by a chaotic pattern of electrical activity throughout the cardiac cycle (Fig. 1A). Organized continuous electrical activity was characterized by a recognizable regular or repetitive pattern (Fig. 1B). Organized continuous electrical activity was more frequently recorded than disorganized continuous electrical activity. Seventeen out of the 20 patients who showed continuous electrical activity had an organized pattern and 6 of the 20 a disorganized pattern. Thus, 3 patients both an organized and disorganized pattern of continuous electrical activity was observed.

Observations on the dynamic behavior of continuous electrical activity: With the catheter positioned in a stable position against the ventricular wall, the dynamic behavior of continuous electrical activity was studied.

Spontaneous disappearance and reappearance of continuous electrical activity without changes in rate of VT, QRS complex morphology or axis: Before an antiarrhythmic drug was given, continuous electrical activity was observed to disappear and reappear spontaneously without change in rate, QRS morphologic pattern or axis of VT in 10 patients (Fig. 2). In 1 other patient, this phenomenon occurred after administration of intravenous procainamide. Spontaneous disappearance of continuous electrical activity occurred in 8 patients in the VT-old MI group and in 2 in the VT-RV dysplasia group.

Pacing-induced transient termination of continuous electrical activity during VT without termination of VT: In 5 patients (4 in the VT-old MI group and 1 patient in the VT-RV dysplasia group) ventricular stimulation during VT could transiently terminate continuous electrical activity (Fig. 3) without terminating VT. This was observed in 1 patient with triple potentials during VT in the aneurysm (Fig. 3), in 3 patients with organized continuous electrical activity (Fig. 4), and in 1 patient with disorganized continuous electrical activity. The phenomenon was induced by 1 to 3 ventricular premature beats in 3 patients, by overdrive ventricular pacing in 1 patient, and both by ventricular premature beats and overdrive pacing in 1 patient.

Continuous electrical activity as a rate-dependent phenomenon during spontaneous or pacing-induced changes in VT rate: In 7 patients (6 in the VT-old MI group and 1 in the VT-RV dysplasia group), continuous electrical activity appeared or disappeared as a rate-dependent phenomenon during spontaneous or pacing-induced changes in VT rate. In 2 patients this occurrred without changes in QRS configuration (Fig. 5).

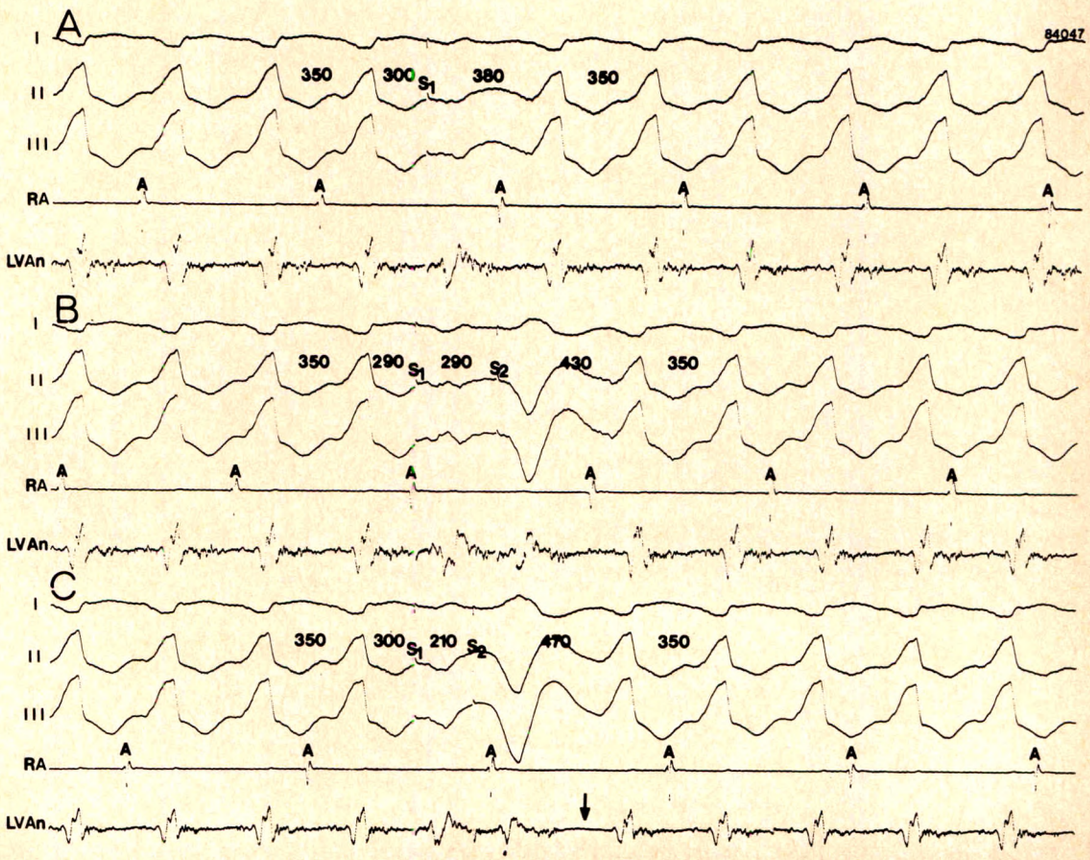

FIGURE 4. Termination of organized continuous electrical activity by premature beats given during ventricular tachycardia (VT). **A,** a ventricular premature beat (S_1) does not terminate continuous electrical activity and VT continues. **B,** 2 ventricular premature beats (S_1, S_2) also fail to terminate continuous electrical activity or VT. **C,** when the interval between S_1 and S_2 is shortened, continuous electrical activity is transiently terminated (**arrow**) without terminating VT.

In the other 5 patients this was observed during changes in VT rate and QRS configuration. Study of the duration of the electrograms during the slowest rate of VT suggested that continuous electrical activity during the fastest VT was probably the result of superposition of similar abnormal electrograms because of the increase in rate. In all 7 patients these observations were made during the organized type of continuous electrical activity.

Continuous electrical activity resulting from Wenckebach-like conduction: In 4 patients continuous electrical activity was simulated by a Wenckebach-like conduction pattern. This phenomenon resulted in an organized pattern of continuous electrical activity, which disappeared spontaneously for a few cycles, to return with regular periodicity (Fig. 6). The 2 closely located recording[s] allowed analysis of this phenomenon because more discrete signals were recorded from 1 pair at the same time that an organized pattern of continuous electrical activity was observed in the other pair of electrodes. In these 4 patients, changes in continuous electrical activity at 1 recording pair of electrodes closely paralleled changes in discrete potentials at the other pair. The fact that conduction block could occur to certain areas resulting in continuous electrical activity or multiple diastolic potentials without influencing the rate or morphologic pattern of VT demonstrates that conduction to these areas was not required to perpetuate VT.

Dependency of continuous electrical activity on the ventricular activation pattern during VT: Continuous electrical activity was not only a rate-dependent phenomenon, but was also critically dependent on the ventricular activation pattern during VT. Minimal changes in QRS morphologic pattern during VT resulted in initiation of the Wenckebach-like sequences

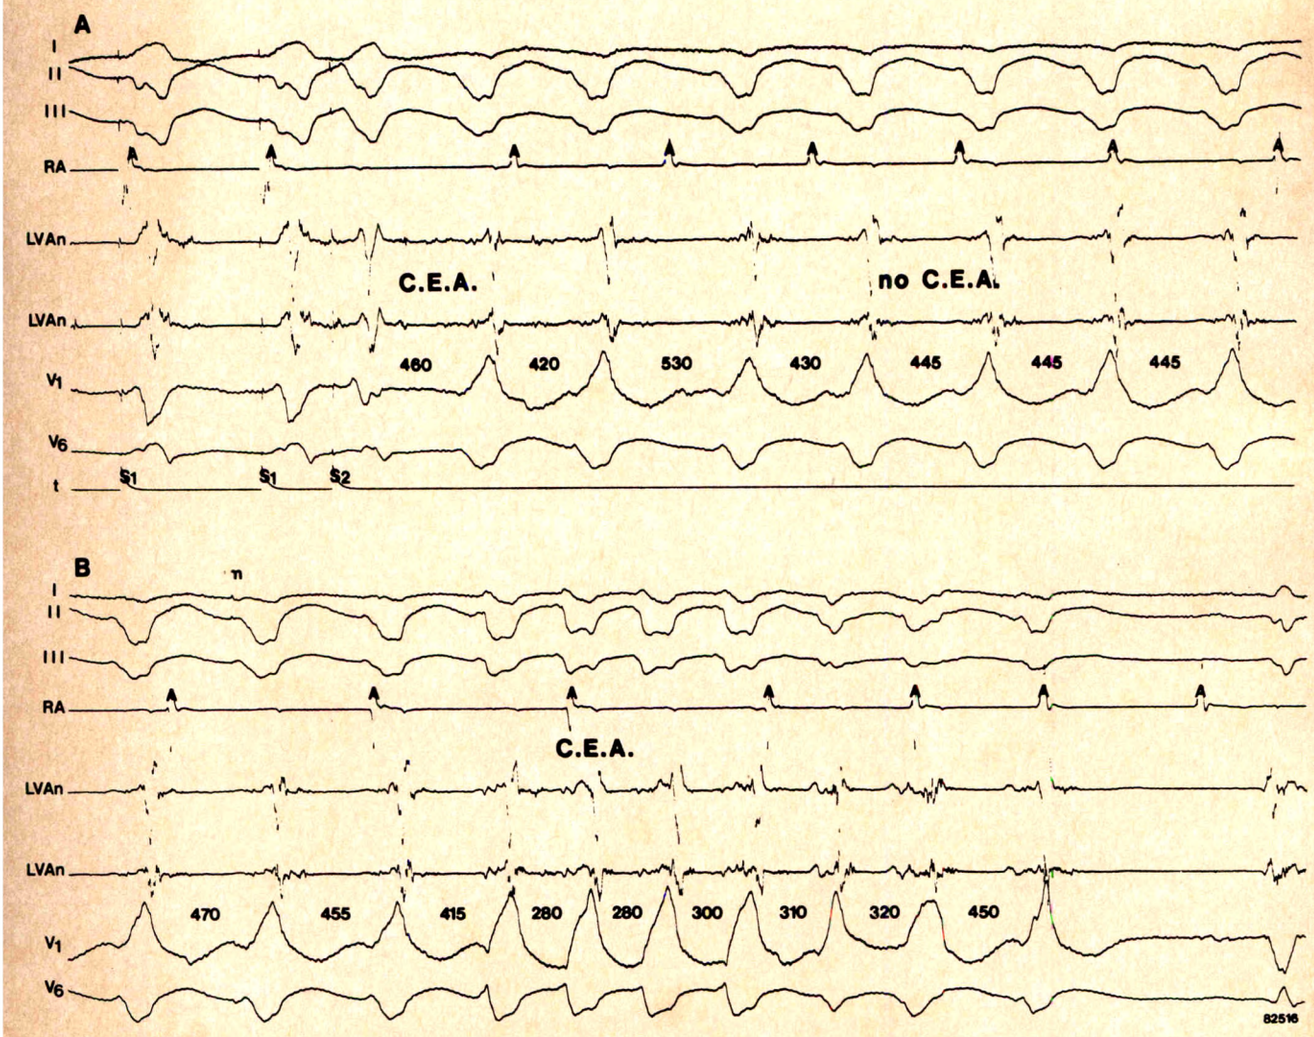

FIGURE 5. Continuous electrical activity (C.E.A.) during ventricular tachycardia (VT) as a rate-dependent phenomenon. **A,** a VT showing marked spontaneous changes in cycle length is initiated by 1 ventricular premature beat given during right ventricular pacing at 120 beats/min. Continuous electrical activity is observed at the onset of VT, but disappears spontaneously after the second VT cycle when the VT cycle length prolongs. **B,** spontaneous termination of the same episode of VT. VT suddenly accelerates before terminating. Continuous electrical activity is observed again when the VT cycle length reaches 280 ms. LVAn = left ventricular aneurysm; RA = right atrium.

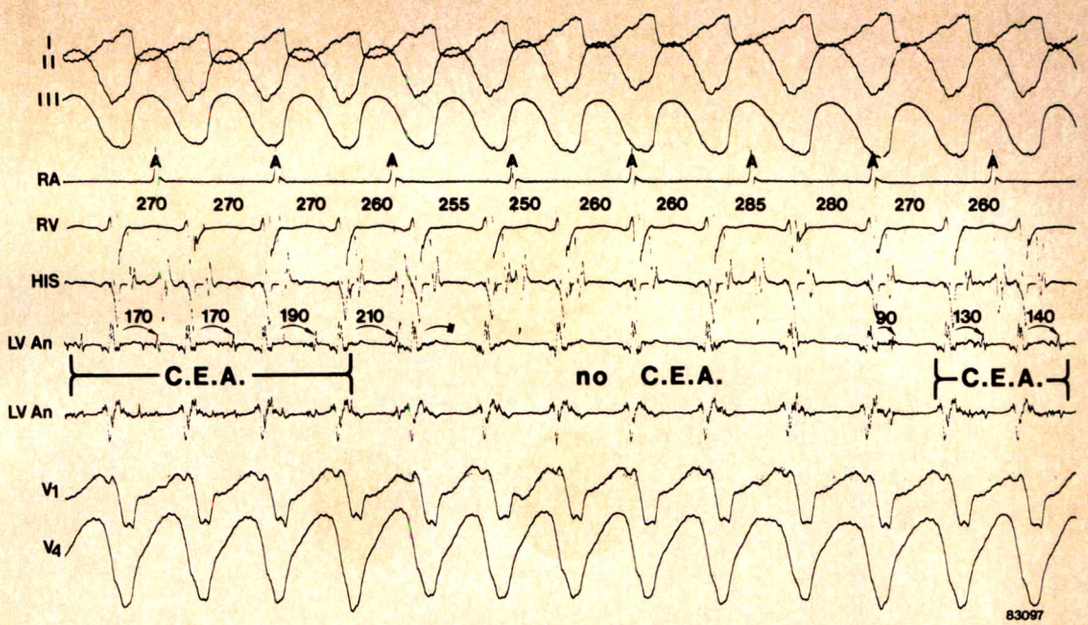

FIGURE 6. Spontaneous appearance and disappearance of continuous electrical activity (C.E.A.) resulting from Wenckebach-like conduction. During a ventricular tachycardia with minimal variations in cycle length (250 to 280 ms), continuous electrical activity is present at the left ventricular aneurysm (LVAn) in the **left** and **right** part of the figure, but absent in the **middle.** Analysis of the electrograms shown in the **top tracing** from the LVAn show a Wenckebach-like conduction pattern. The intracavitary potentials are stable. The Wenckebach-like sequence starts again in the **right** part of the tracing.

of conduction to areas not required to perpetuate VT. A combination of a rate-dependent phenomenon, change in the ventricular activation pattern during VT and Wenkebach-like conduction to areas not required to perpetuate VT has therefore to be considered to explain the observations made in the patient shown in Figure 7.

Pacing-induced change from noncontinuous electrograms into continuous electrical activity without the prevention of termination of VT: In 2 patients during overdrive ventricular pacing, electrograms that were noncontinuous during VT could be changed into continuous electrical activity by rapid ventricular pacing from the right ventricle. However, this did not prevent termination of VT (Fig. 8). This was probably a rate-dependent phenomenon that also depended on the ventricular activation pattern (the QRS being different during pacing as compared to VT) and widening of the electrograms during rapid pacing.

Termination of continuous electrical activity by antiarrhythmic drugs without termination of VT: In 7 patients an antiarrhythmic drug was given intrave-

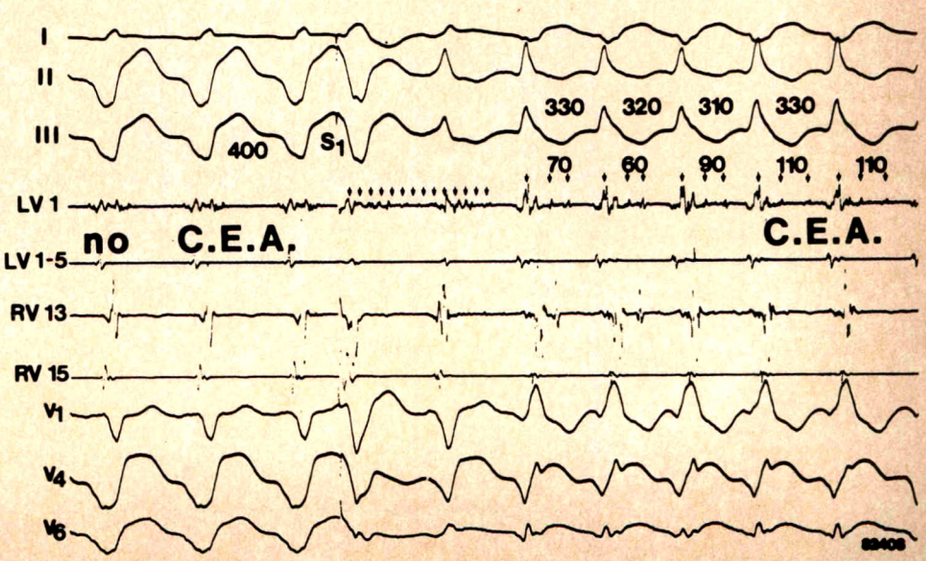

FIGURE 7. Left, a ventricular tachycardia with left bundle branch block morphologic pattern, left-axis deviation, and a cycle length of 400 ms. Continuous electrical activity (C.E.A.) is not observed at the left ventricular (LV) recording site 1 (aneurysm) or site 1–5 (border zone). A single ventricular premature beat (S_1) initiates transient continuous electrical activity at LV1 and results in another ventricular tachycardia with right bundle branch block morphologic pattern, right axis in the frontal plane and a cycle length of 310 to 330 ms. Progressive fragmentation and delay in the electrograms at LV1 are observed, resulting in continuous electrical activity in the last cycles. RV13, RV15 = right ventricular sites.

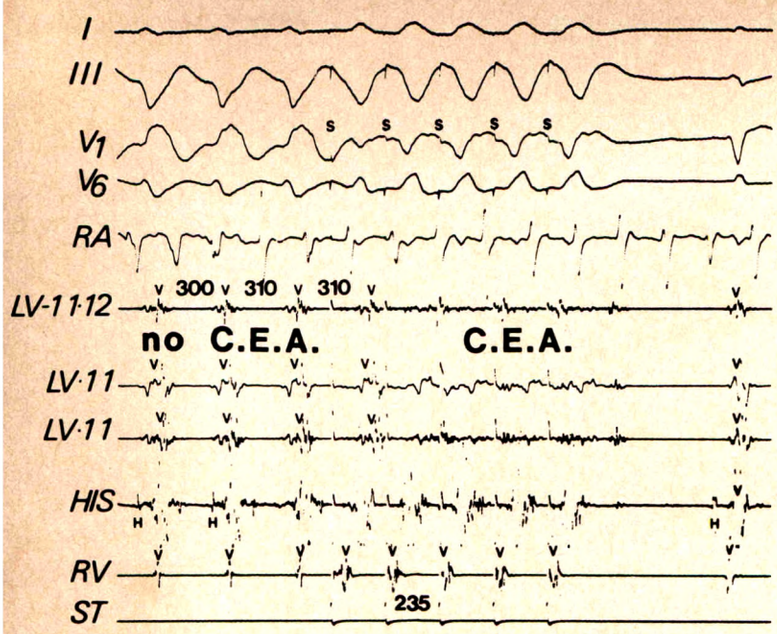

FIGURE 8. Change of noncontinuous electrograms into continuous electrical activity (C.E.A.) by overdrive ventricular pacing during ventricular tachycardia (VT) without preventing termination of VT. **Left,** a VT with a right bundle branch block morphologic pattern, left axis in the frontal plane and a cycle length of 300 to 310 ms. Overdrive ventricular pacing from the right ventricular (RV) apex with a cycle length of 235 ms is done for 5 beats. The electrograms at left ventricular (LV) recording sites 11 and 11–12 change from noncontinuous during VT to continuous electrical activity during overdrive ventricular pacing. These potentials widen and span markedly diastole after the last paced complex. However, initiation of continuous electrical activity did not prevent pacing termination of VT.

nously during VT at the time of recording of continuous electrical activity. Two patients received intravenous amiodarone, 2 procainamide, 1 patient disopyramide, and 2 propafenone. In 3 patients (1 receiving amiodarone, 1 disopyramide and 1 propafenone), continuous electrical activity terminated without reappearing during the slowing in rate of VT (Fig. 9). This was associated with marked changes in the morphologic pattern of the potentials. However, VT continued with the same QRS morphologic pattern and axis. In 1 other patient, continuous electrical activity disappeared and reappeared spontaneously after intravenous procainamide, demonstrating that continuous electrical activity was not essential to perpetuate the arrhythmia.

Relation between the areas showing continuous electrical activity during VT, recordings during sinus rhythm and ventricular anatomy: In all 20 patients who had continuous electrical activity during VT, correlation with the ventricular anatomy revealed that continuous electrical activity was recorded within the aneurysm. No patient showed continuous electrical activity over areas with normal wall motion. Recordings during sinus rhythm over the area that showed continuous electrical activity during VT were invariably abnormal. In all patients, low-amplitude potentials (in 19 patients less than 1 mV) lasting 50 ms or more were recorded. These potentials continued after the end of the QRS complex in the surface leads.

Abnormal potentials during sinus rhythm were not recorded in any patient in the idiopathic-VT group.

Continuous electrical activity was recorded in the coronary sinus in 3 patients. All 3 had an inferoposterior wall MI with a large aneurysm (Fig. 10).

Discussion

In 1978, Josephson et al[17] described the phenomenon of continuous electrical activity during endocavitary left ventricular mapping in patients with sustained, monomorphic VT. In that report and subsequent reports they did not report how often continuous electrical activity could be recorded in these patients. Our study in 56 patients showed the presence of electrical activity bridging 2 consecutive QRS complexes during monomorphic VT in 36% of patients with VT-old MI, 83% of patients with VT-RV dysplasia, and its absence in patients with idiopathic VT. In 17 of 20 patients, study of the dynamic behavior of continuous electrical activity revealed that electrical activity resembling continuous electrical activity was a transient phenomenon or could be terminated without resulting in termination of VT. To our knowledge, this transient form of continuous electrical activity has not been described previously and illustrates the need for careful study of the dynamic behavior of continuous electrical activity before giving it mechanistic significance. The type of continuous electrical activity recorded in our study was not essential to perpetuate VT in 17 of 20 patients. In the remaining 3 patients, continuous electrical activity persisted during VT and could not be terminated. This does not prove, however, that continuous electrical activity was essential to perpetuate the arrhythmia.

Our investigation was directed by the "intention-to-record" continuous electrical activity. Although careful mapping during VT was performed the actual incidence of continuous electrical activity in our 56 patients must be interpreted with caution. The difficulties to reach certain left ventricular areas of the heart by a catheter technique are well known. We believe that the real incidence of continuous electrical activity in patients with VT-old MI is higher than the one we documented. The absence of continuous electrical activity from areas showing normal wall motion in the VT-old MI and VT-RV dysplasia groups strengthens the observations made in the idiopathic-VT

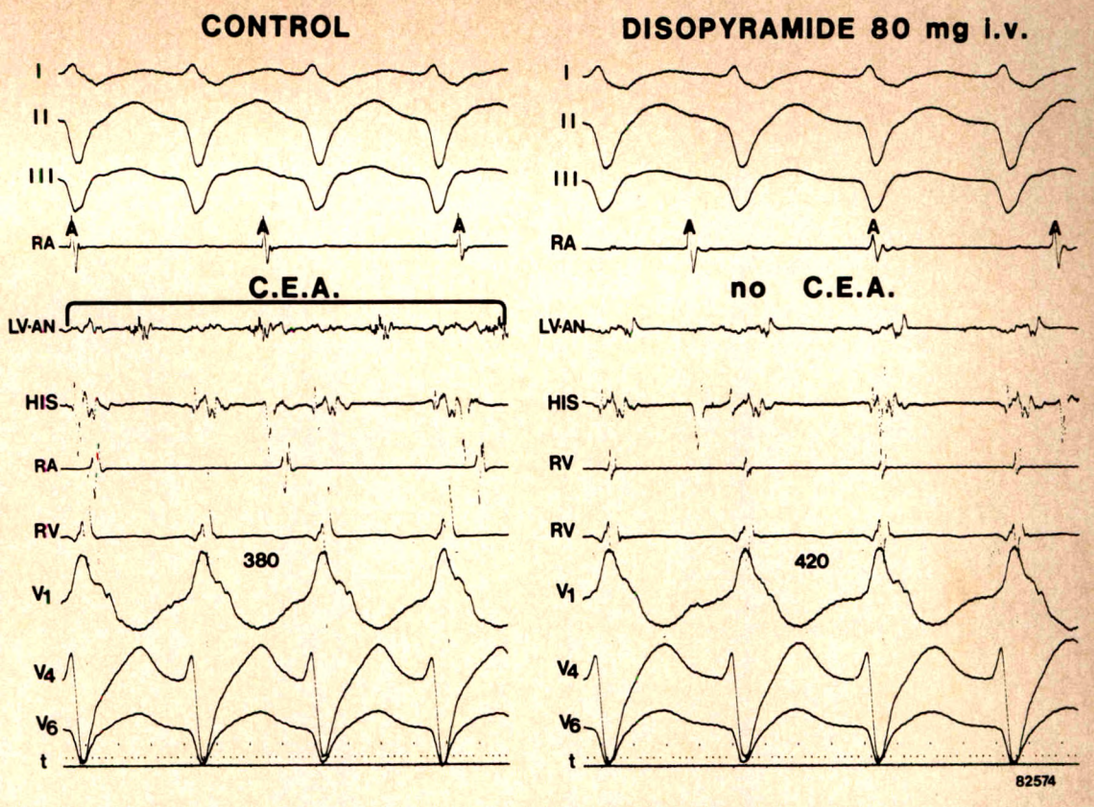

FIGURE 9. Termination of continuous electrical activity (C.E.A.) by intravenous administration of disopyramide without terminating ventricular tachycardia (VT). **Left,** continuous electrical activity at the left ventricular aneurysm (LV-An) during VT with a cycle length of 380 ms. The catheter was stabilized in this position and continuously checked. Disopyramide was given intravenously. The VT cycle length lengthened to 420 ms and a marked change in the morphologic pattern of the potentials recorded occurred, with termination of continuous electrical activity. Disappearance of continuous electrical activity at this recording site did not prevent perpetuation of VT with the same QRS morphologic pattern and axis. Both panels were recorded during the same episode of VT. RA = right atrium.

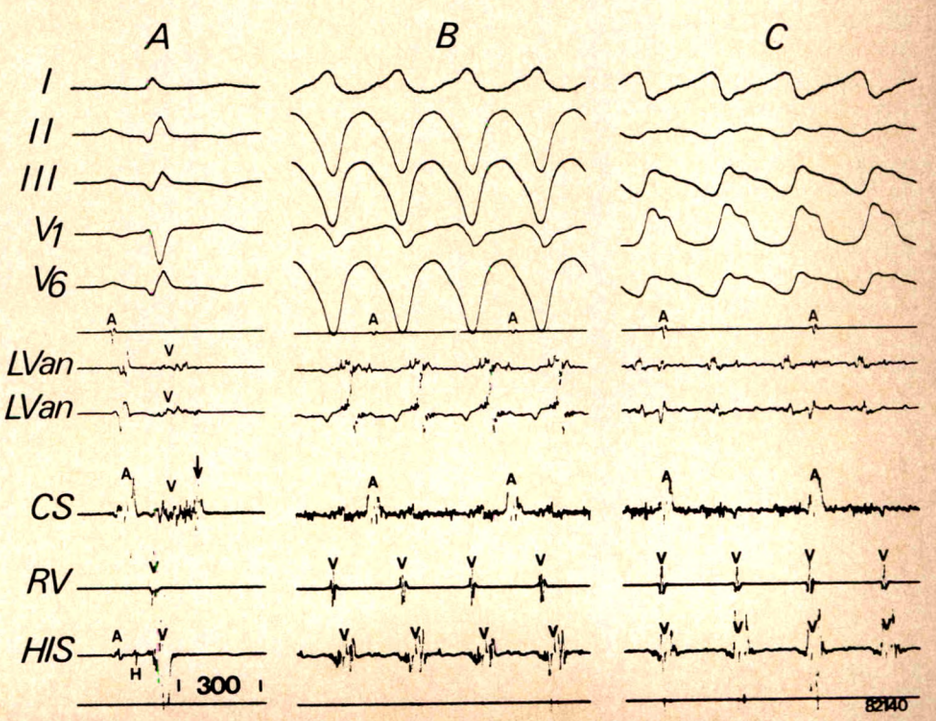

FIGURE 10. An organized pattern of continuous electrical activity is observed during 2 morphologically distinct monomorphic ventricular tachycardias in the coronary sinus (CS) in a patient with an inferoposterior myocardial infarction. **A,** recordings during sinus rhythm show abnormal potentials at the left ventricular aneurysm (LVAn) and at the CS (**arrow**). **B** and **C,** continuous electrical activity is observed during ventricular tachycardia in the CS, and in panel **C** in the LVAn.

group. Continuous electrical activity was not found in any patient from the last group. This may indicate that our recording techniques were not refined enough to record from abnormal areas too small to be identified by angiography, or simply that continuous electrical activity was indeed absent in patients with idiopathic VT and in areas with normal ventricular muscle. Further elucidation of these problems can only be obtained during careful, visually directed mapping of the open heart.

The present study has obvious limitations. Apart from our inability to record from all ventricular areas, catheter mapping is an imprecise method. The amplification and filter settings used in our study may have markedly influenced our results.[18] We did not compare different filter settings and all recordings were bipolar. Only endocardial mapping was performed in these patients. Therefore, we do not know what was occurring at the intramural or epicardial level during VT. Although the electrode catheter was held in the same position, some of our observations could have been the result of slight changes in catheter position. Often, the 2 closely recorded bipolar electrograms showed marked differences. Our only proof for stability in catheter position is the reproducibility of the recorded electrograms. These limitations, however, do not invalidate the observations made on the dynamic behavior of continuous electrical activity, because the filter setting or gain were not changed at the time of recording of these phenomena.

Ideker et al[15] showed that late fractionated potentials and continuous electrical activity can be caused by electrode motion. They stated that "additional evidence should be presented to indicate that the potentials are not caused by motion at the electrode-tissue interface. Such additional evidence could be a change in the late potentials during the beginning or end of an arrhythmia in the absence of a change in heart motion, Mobitz type I or II block in the delayed potentials, or loss of continuous electrical activity with ventricular pacing at the same rate as the tachycardia." We observed that continuous electrical activity could disappear and reappear spontaneously during VT without any change in rate or QRS morphologic pattern during VT. Thus, motion at the electrode-tissue interface as a causal mechanism is very unlikely. Continuous electrical activity could also be terminated by pacing without terminating VT. In some patients with marked spontaneous or pacing-induced variations in rate of VT, continuous electrical activity was a rate-dependent phenomenon present at the initiation of the arrhythmia and after acceleration of tachycardia. Continuous electrical activity also depended on the ventricular activation pattern during VT, and was produced in some patients by Wenckebach-like conduction patterns to areas not required to perpetuate VT. This last observation is similar to that reported by Rosenfeld and Batsford[19] in a patient with RV dysplasia. Continuous electrical activity could be produced by ventricular pacing in areas showing noncontinuous electrograms during VT without preventing the termination of VT. Finally, continuous electrical activity could be terminated by administration of antiarrhythmic drugs without terminating VT which continued at a slower rate with the same QRS morphologic pattern. At least one of the these phenomena were observed in all but 3 patients. The transient disappearance or termination of continuous electrical activity with perpetuation of VT in 17 of our 20 patients indicates that continuous electrical activity was not essential to perpetuate VT.

We did not include in this study patients with ventricular fibrillation or polymorphic VT. The continuous changes in ventricular activation pattern and rate in these arrhythmias would have made it impossible to assess the dynamic behavior of continuous electrical activity.

Continuous electrical activity was recorded only from abnormal areas of the heart where abnormal potentials were observed during sinus rhythm. As with the patients described by Josephson et al,[17] all of our patients with continuous electrical activity showed, during sinus rhythm, potentials that continued after the end of the QRS complex in the area where continuous electrical activity was observed. The reverse was, not true, however. In all patients in the VT-old MI group, late potentials were recorded during sinus rhythm. In only 15 patients was continuous electrical activity recorded during VT.

The hypothesis that continuous electrical activity during VT represents recording from a reentry circuit has been questioned.[7,14,15] Wit et al[7] and Gallagher et al[14] stressed that continuous electrical activity may represent a "bystander" phenomenon recorded from areas with abnormal conduction, but not essential to perpetuate VT. Our observations support this hypothesis in 17 of the 20 patients studied. It can be argued that the continuous electrical activity recorded in our study differs from that observed by other investigators. There is no clear definition of continuous electrical activity. It was by observing the dynamic behavior of continuous electrical activity that its transient nature was recognized. When recording at areas showing continuous electrical activity had been made for only a few beats, or pacing or drugs would not have been used, our observations would have been identical to those of other investigators. Continuous electrical activity was never recorded during sinus rhythm. When VT terminated, continuous electrical activity was no longer present. One might have incorrectly concluded that continuous electrical activity was essential to perpetuate VT.

In conclusion, the recording of continuous electrical activity with a 1-cm interelectrode distance bipolar catheter is a frequent phenomenon during monomorphic VT. Study of the dynamic behavior of continuous electrical activity shows that it represents electrical activity from abnormal heart areas, not necessarily required to perpetuate VT. Detailed studies in the experimental and clinical laboratory are required to assess the significance of the different types of local electrical activity that can be observed during VT in the human heart.

Arrhythmias Induced During Termination of Supraventricular Tachycardia

BERND WALDECKER, MD, PEDRO BRUGADA, MD, KAREL den DULK, MD, MANFRED ZEHENDER, MD, and HEIN J. J. WELLENS, MD

Pacing is being used frequently for the treatment of drug-resistant, paroxysmal supraventricular tachycardias (SVT). SVT can usually be terminated by pacing, but arrhythmias may be induced which interfere with the safety of antitachycardia pacing. To quantify these pacing-induced arrhythmias, 453 attempts to terminate SVT in 111 patients were analyzed. The patients were 6 to 73 years old (mean 41); 62 were male. Seventy-six patients had SVT using an accessory atrioventricular bypass, and 35 patients had intranodal SVT. Single and then, if required, multiple ventricular and atrial premature beats and overdrive pacing were delivered from the atrium and ventricle. A pacing-induced arrhythmia occurred in 9% of all attempts (34% of patients). Atrial flutter or fibrillation (AF) was the most frequent arrhythmia (in 8% of all attempts and sustained in 75%). Atrial vs ventricular pacing resulted in a 12% vs 2% incidence of AF. AF was unrelated to age, sex, atrial size and SVT type, and was predominantly induced by multiple premature beats. In 6 patients a different SVT and in 2 patients a nonsustained ventricular tachycardia was induced. In 6 patients SVT could only be terminated by initiating another arrhythmia. Thus, AF is frequently induced during attempted pacing termination of SVT. To limit the risk of AF, a single premature beat should preferentially be used to terminate SVT. In 6% of patients, SVT can only be terminated by inducing another arrhythmia. Therefore, careful investigation of the properties of the clinical SVT by programmed electrical stimulation of the heart is mandatory before considering pacing as therapy for these patients. (Am J Cardiol 1985;55:412–417)

Reentrant tachycardia can usually be initiated and terminated by pacing. A premature, artificially induced depolarization delivered to tissue sustaining the circulating impulse can produce a block in impulse conduction and terminate circus movement. After the initial report of Durrer et al[1] of the ability to initiate and terminate reentrant supraventricular tachycardia (SVT) by properly timed atrial (APB) or ventricular premature beats (VPB), antitachycardia pacing was introduced into clinical cardiology as a new method of treating drug-resistant tachycardias. Whereas Lister et al[2] used an external pacemaker to interrupt SVT by overdrive atrial pacing, Ryan et al[3] used an implanted demand pacemaker, which was converted to an asynchronous underdrive pacing mode by placing the magnet over the pacemaker, thereby giving a single VPB to terminate SVT in a patient with the Wolff-Parkinson-White (WPW) syndrome. Subsequently, several implantable pacemaker systems, which can recognize and terminate tachycardia, have been developed. However, even in the first reports[4–8] of antitachycardia pacing, unwanted arrhythmias were already being described as a possible complication of this form of therapy. To assess these pacing-induced arrhythmias, we analyzed arrhythmias that were induced during attempted pacing termination of SVT in patients with circus-movement tachycardia using an accessory atrioventricular bypass tract and in patients with intranodal tachycardia.

Methods

Patients: Data from 111 consecutive patients with documented paroxysmal SVT were retrospectively analyzed. All patients gave informed consent before the electrophysiologic investigation. In all patients sustained SVT was initiated by programmed electrical stimulation. Their clinical data are listed in Table I. The patients represented a general referral group and were studied for diagnostic (palpitations without documented arrhythmia), therapeutic (drug-resistant SVT) or prognostic reasons (WPW syndrome with short bypass tract refractory period). Seventy-six patients had atrioventricular

APB = atrial premature beat; AOP = atrial overdrive pacing; VOP = ventricular overdrive pacing; VPB = ventricular premature beat; – = none; other abbreviations as in Table I.

(AV) junctional SVT using an accessory bypass as 1 limb of the circuit; in 27 of these patients the bypass was concealed. Thirty-five patients had intranodal SVT. Only 2 patients had structural heart disease, both with coronary heart disease. Eleven patients were studied before and during antiarrhythmic drug treatment (amiodarone in 1, encainide in 2, sotalol in 4, propafenone in 3 and disopyramide in 1). Thirteen patients were investigated only while receiving antiarrhythmic drugs orally (amiodarone in 9, encainide in 3 and lorcainide in 1). Our previously described method of stimulation and recording was used.[9] Electrode catheters were placed at the right atrium, coronary sinus, His bundle area and right ventricular apex. During sustained SVT, premature beats and overdrive pacing were attempted from the atrium and ventricle. Each pacing method was considered as a separate attempt to terminate SVT in an individual patient, however, repetition of the same pacing method was considered as 1 attempt. Four hundred fifty-three attempts to terminate SVT were performed in these 111 patients (mean 4 attempts per study) (122 studies in 111 patients). Single late APBs or VPBs were delivered first, scanning the tachycardia cycle in 10-ms decrements. The premature beat was given after every 6 to 8 tachycardia beats until SVT was terminated, the paced tissue was refractory, or another arrhythmia occurred. Only if a single premature beat at the particular stimulation site failed to terminate SVT and did not initiate an arrhythmia was a second or, if required, a third APB or VPB given. Twenty-beat bursts of overdrive pacing were begun at a rate 10 beats faster than the tachycardia rate, and the pacing rate increased by 5 to 10 beats/min until SVT was interrupted or another arrhythmia initiated. A particular attempt was considered successful only if it never failed to terminate SVT and never initiated another arrhythmia.

The current strength was twice diastolic threshold and the stimulus duration 2 ms. Stimulation was always bipolar.

The size of the left atrium was measured echocardiographically in accordance with the recommendations of the American Society of Echocardiography.[10]

Results

The mean SVT cycle length for the whole group of patients was 365 ms (range 250 to 540). In 34% of all patients (38 of 111) or in 9% of all 453 attempts to terminate SVT, an arrhythmia was induced. The distribution of pacing-induced arrhythmias within the different groups of patients and attempts is shown in Table II. The most frequent pacing-induced arrhythmia was atrial fibrillation or atrial flutter (AF), which occurred in 8% of all attempts and in 30% of patients (Fig. 1). During attempts to terminate SVT by atrial pacing the incidence of AF was 12%, vs 2% during ventricular pacing. Increasing numbers of premature beats raised the risk of AF from 11% (1 APB) to 18% (2 APBs) to 22% (3 APBs) during atrial stimulation and from 1% (1 VPB) to 5% (2 VPBs) during ventricular stimulation (Fig. 2). AF occurred during overdrive pacing from the atrium in 5% of the attempts (2 of 43), but never after ventricular overdrive pacing (18 attempts). There was no difference in the incidence of AF in patients with concealed accessory bypasses compared with patients with the

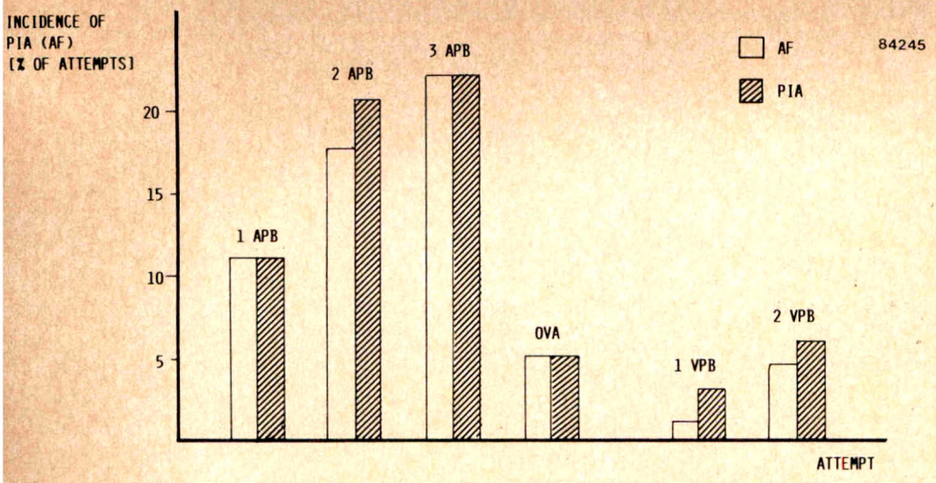

FIGURE 1. Incidence of all pacing-induced arrhythmias (PIA) and of atrial fibrillation/flutter (AF) according to the mode of attempted termination and in relation to the number of attempts performed. Ventricular overdrive pacing never resulted in a pacing-induced arrhythmia and is not illustrated. APB/VPB = atrial/ventricular premature beats; OVA = atrial overdriving.

WPW syndrome, or in all patients with bypasses compared with patients with intranodal SVT ($p > 0.05$). There was no relation between either risk of AF and patient age ($p > 0.05$) or gender ($p > 0.05$). If the cycle length of the SVT was longer than 340 ms, induction of AF was a significantly less frequent event ($p < 0.05$). This was not the result of easier termination of slower SVT by fewer premature beats ($p > 0.05$). The incidence of pacing-induced AF did not differ significantly between untreated patients and patients treated with antiarrhythmic drugs (8.5 vs 5%, $p > 0.05$). AF was sustained (lasting longer than 30 seconds) in 75% of episodes. Injection of an antiarrhythmic drug terminated AF in 2 patients, and successful atrial overdrive pacing of flutter was performed in 5 patients; the study was interrupted 3 times, and in 3 patients, including 1 with WPW syndrome and a rapid ventricular response, AF was cardioverted. The remaining self-terminating episodes of AF lasted for a mean of 5 minutes (range 35 seconds to 20 minutes). Untreated patients with the WPW syndrome had the shortest RR intervals during AF, ranging from 400 to 175 ms; half (8 of 15) had the shortest RR intervals (shorter than 270 ms [220 beats/min]) and 3 of 15 had the shortest RR intervals (shorter than 200 ms [300 beats/min]). Only 3 patients with the WPW syndrome had AF in the presence of antiarrhythmic drugs; their shortest RR intervals were 270, 300 and 350 ms. Spontaneous AF was documented or suspected in 21 patients, but AF was not induced more frequently in them than in the rest of the group ($p > 0.05$). Resumption of the previous SVT after spontaneous termination of AF was seen in 5 patients.

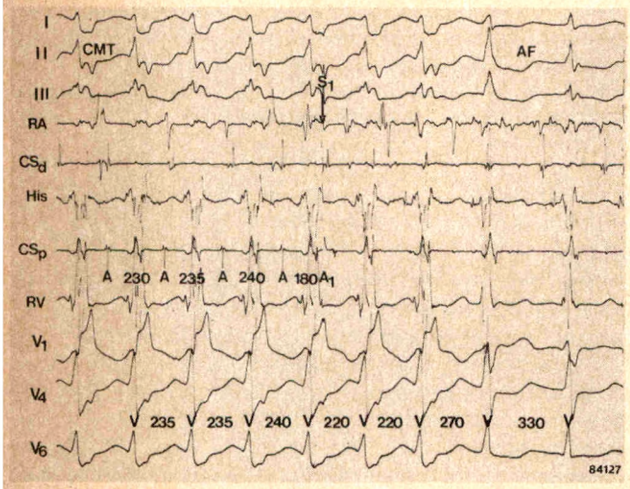

FIGURE 2. Initiation of atrial fibrillation/flutter (AF). During atrioventricular junctional supraventricular tachycardia using a right-sided accessory bypass retrogradely (labeled CMT) with a mean cycle length of 235 ms, an atrial premature beat (A_1) delivered in the high right atrium (RA) induces AF. Atrioventricular conduction predominantly through the atrioventricular node, shortest RR interval, 220 ms. A = atrial deflection; CMT = atrioventricular junctional supraventricular tachycardia; CS_d, CS_p, His, RA, RV = intracardiac recordings from the distal and proximal coronary sinus, His bundle area, high right atrium and right ventricle, respectively; H = His bundle deflection; S = stimulus artifact; V = ventricular complex.

M-mode echocardiograms were available in 66 patients. Left atrial enlargement was present in 8 (12%). The largest atrial size was 48 mm; the maximal left atrial/aortic root ratio was 1.41. The occurrence of pacing-induced AF and left atrial size was unrelated ($p > 0.05$).

In 2 untreated patients, 1 of them with AV junctional SVT using a left-sided accessory bypass, the other with intranodal SVT, a nonsustained ventricular tachycardia (shorter than 30 seconds) developed after 1 and 2 VPBs during SVT, respectively. The first patient, an otherwise healthy 40-year-old man, had 9 beats of polymorphic ventricular tachycardia followed by a monomorphic tachycardia that lasted 11 seconds (Fig. 3). The second patient had a run of nonsustained polymorphic ventricular tachycardia (10 beats).

In 2 patients, 2 APBs changed antidromic into orthodromic AV junctional SVT and was sustained in 1. In 3 other patients with AV junctional SVT during use of an accessory bypass who had dual AV nodal pathways, intranodal SVT was induced by advancing atrial activation either directly by an APB or by retrograde conduction over the accessory bypass following a VPB. Earlier atrial activation found the fast AV nodal pathway refractory, allowing anterograde conduction

solely over the slow AV nodal pathway initiating intranodal SVT. In 1 patient, an APB as well as a VPB during AV junctional SVT induced intranodal SVT (Fig. 4). In 2 of these 3 patients, the induced intranodal SVT was sustained. In another patient with AV junctional SVT, atrial overdrive pacing initiated a sustained atrial tachycardia, which had been clinically documented. In 7 of 111 patients (6%), SVT could be terminated only by initiating another arrhythmia. In these patients all attempted pacing modalities either did not interrupt the SVT or resulted in an arrhythmia; the arrhythmia was AF in 6 patients and intranodal SVT in 1. However, in most patients in whom a pacing-induced arrhythmia occurred, a pacing mode could be found that terminated SVT without initiating a subsequent arrhythmia.

Discussion

Antitachycardia pacemakers have undergone important refinements to obtain greater versatility in recognizing and terminating SVT automatically or by patient-activated system.[11] Termination should be achieved as quickly and as safely as possible. Pacing-induced arrhythmias are an undesirable complication of the electrical treatment of paroxysmal SVT.[5,6,12–14] Antitachycardia pacemakers use 1 or several of the following pacing modalities to terminate SVT: (1) Single extrastimuli with either a fixed coupling interval or scanning the tachycardia cycle to find a zone of termination; scanning can be random, such as underdrive pacing, or the coupling interval can be changed by a predetermined interval. (2) Scanning with 2 or more extrastimuli. (3) Increasing number of extrastimuli at fixed or adaptive intervals until SVT is interrupted. (4) Overdrive pacing with fixed, adaptive or variable intervals between the trains of stimuli.[15]

Whenever pacing is performed, however, nonclinical arrhythmias can be initiated. We observed that during attempted pacing termination of SVT, AF was the most common pacing-induced arrhythmia. As expected, atrial stimulation yielded a considerably higher incidence of AF than stimulation in the right ventricular apex, but ventricular stimulation during SVT still resulted in a 2% incidence of AF. Regardless of the stimulation site, the risk of AF increased with the number of premature beats. Initiation of AF during ventricular stimulation in 3 patients was the result of rapid retrograde VA conduction over an accessory bypass tract resulting in premature atrial stimulation. In 1 patient, 2 VPBs during intranodal SVT induced AF. However, in this patient, an accessory bypass not participating in the SVT could not be definitely excluded. The incidence of AF during SVT may have been higher if multiple APBs had been given systematically to each patient. Although multiple APBs were given frequently, for the purpose of this study they were analyzed only if a single APB failed to terminate SVT and did not result in another arrhythmia. We did not observe a significant difference in the incidence of AF in patients with AV junctional SVT and in patients with intranodal SVT, although it has been suggested that enhanced atrial vulnerability exists in patients with the WPW syndrome.[16]

Atrial overdrive pacing was not as prone to induce AF as suggested by other studies. We found an incidence of 5%, which is much lower than the 17.5% incidence reported by other investigators.[13] Two variations in population and pacing modes may have accounted for these differences. First, overdrive pacing was attempted during SVT after giving premature beats. Second, our initial pacing cycle length was only 5 to 10 ms shorter than the tachycardia cycle length and was shortened in steps of 5 to 10 beats/min until termination of SVT.

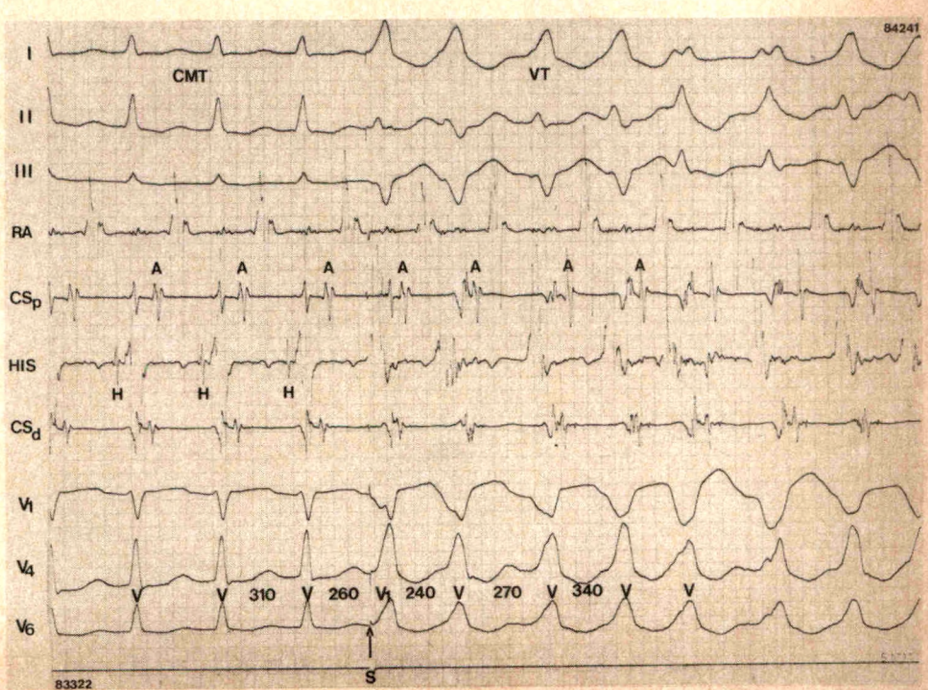

FIGURE 3. Induction of nonsustained ventricular tachycardia (VT). A ventricular premature beat (V_1) given in the right ventricular apex during atrioventricular junctional tachycardia (labeled CMT) using a left-sided accessory bypass induces (nonsustained) polymorphic VT. Abbreviations as in Figure 2.

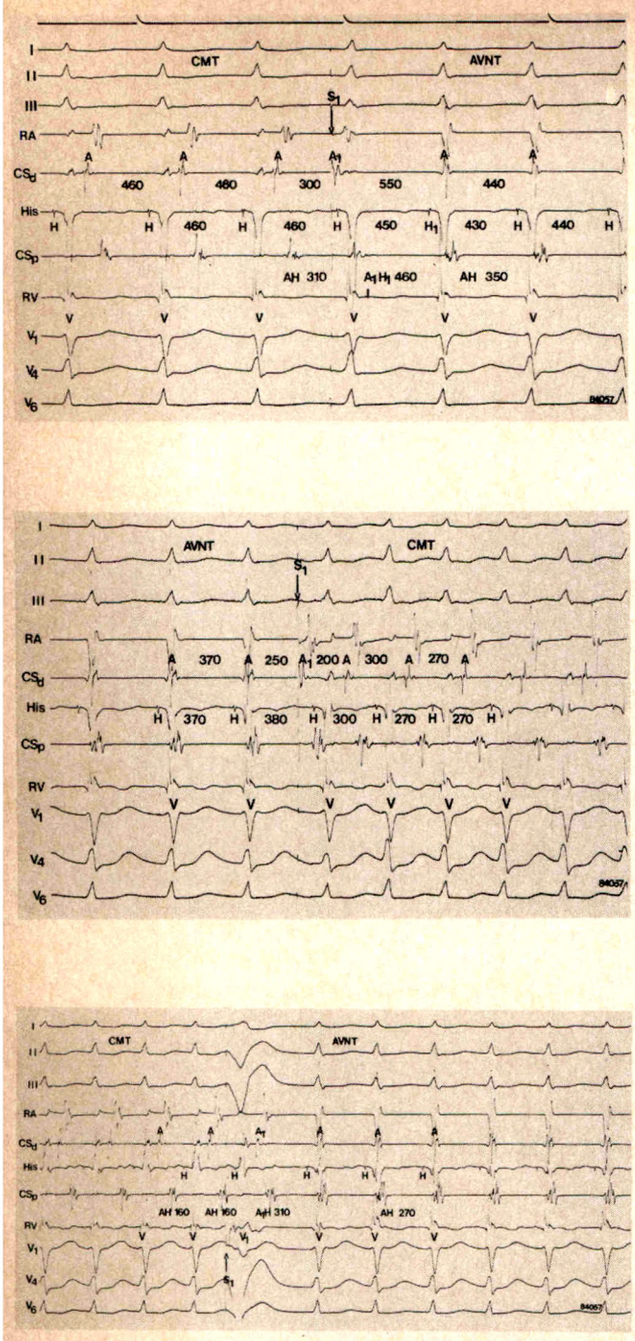

FIGURE 4. Inability to terminate supraventricular tachycardia (SVT) by premature beats from the atrium (**top** and **middle**) and the ventricle (**bottom**) in a patient with an accessory atrioventricular (AV) bypass and dual AV nodal pathways. Atrial flutter/fibrillation was also initiated in this patient by rapid atrial pacing. **Top,** 1 atrial premature beat (S_1) given in the distal coronary sinus (CS_d) during AV junctional SVT renders the atrium refractory for the subsequent retrograde activation over the accessory bypass, enters the slow AV nodal pathway, allowing the fast pathway to recover, and thereby initiates intranodal SVT. **Middle,** 1 atrial premature beat (S_1) given in the CS_d during intranodal SVT collides within the fast AV nodal pathway, blocks anterogradely in the slow AV nodal pathway and allows resumption of AV junctional SVT. **Bottom,** 1 ventricular premature beat during AV junctional SVT advances atrial activation over the accessory bypass and penetrates the fast AV nodal pathway retrogradely. Subsequent ventricular activation occurs over the slow AV nodal pathway and initiates intranodal SVT. Abbreviations as in Figure 2.

This may be less likely to initiate AF than overdrive pacing at a faster initial pacing rate.

Pacing during tachycardias faster than 175 beats/min resulted in a higher incidence of AF than pacing during tachycardias slower than 175 beats/min. This difference in the incidence of AF was not the result of termination of slower SVT by fewer extrastimuli.

During pacing-induced AF, we observed short RR intervals due to rapid AV conduction over the accessory bypass in patients with the WPW syndrome, but we did not observe collapse or initiation of ventricular fibrillation in any of these patients as previously reported.[17–20] However, reinitiation of AV junctional SVT was observed in 5 patients when pacing-induced AF terminated spontaneously.[16]

In 3 patients, AV junctional SVT was exchanged for intranodal SVT during attempted pacing termination. This could occur because of the presence of dual AV nodal pathways. We found dual AV nodal pathways in 18 of 76 patients (24%) with an accessory bypass. Although only 3 of these 18 patients also had intranodal SVT induced during attempted termination, in 1 patient AV junctional SVT was repeatedly changed into sustained intranodal SVT by APB and VPB and could not be reproducibly terminated by pacing.

APB changed antidromic AV junctional SVT into orthodromic SVT in 2 patients and nonsustained ventricular tachycardia was induced by VPB in another 2 subjects; in all 4, however, an effective and safe mode of pacing termination was subsequently found.

In 66 of 111 patients in whom echocardiograms were available, left atrial size was normal and unrelated to the incidence of AF.

Although we observed a pacing-induced arrhythmia due to attempted termination of SVT in 34% of patients, in most of them an alternative, safe and reliable mode of interruption of SVT by pacing was found. Of this series of 111 consecutive patients, SVT could not be terminated by APBs, VPBs or overdrive pacing in 7 patients (6%) without initiating another arrhythmia, which was AF in 6. Antitachycardia pacing should not be considered for these patients.

Our results concerning pacing-induced arrhythmias were obtained during electrophysiologic investigation in the catheterization laboratory. Comparison between our findings and clinical antitachycardia pacing with implantable pacemakers is not established, and a strict correlation should be assumed only with caution. For instance, our group represents a general referral group. The incidence of pacing-induced arrhythmias may have been underestimated due to easier termination of SVT in these patients than in patients with drug-resistant SVT. Drug-resistant SVT may be faster or more difficult to terminate, thus increasing the likelihood of inducing another arrhythmia.

We conclude that attempted termination of SVT by pacing results in initiation of another arrhythmia in up to 34% of patients. Of these, AF is the most common and occurs in up to 30% of patients and is sustained in 75%. Ventricular stimulation during SVT can induce nonsustained ventricular tachycardia. Careful evaluation

of the nature and consequences of these arrhythmias, particularly in patients with the WPW syndrome and a short anterograde refractory period of the accessory pathway, is mandatory before instituting ATP for the treatment of paroxysmal SVT. In most of these patients, however, a pacing mode can be found that will reliably and safely terminate SVT. In 6% of the patients, the tachycardia can be terminated only by initiating another arrhythmia. These patients are not candidates for antitachycardia pacing.

Maximal Hand Blood Flow in Hypertensive and Normal Subjects

DAVID HORWITZ, MD, and DALI J. PATEL, MD, PhD

The present study examined whether patients with systemic hypertension have evidence of structural vascular changes, whether such changes can be detected in early stages of hypertension and whether they are reversible with treatment. Hypertensive and normal subjects were studied under conditions of maximal vasodilation in which flow at a given driving pressure was considered to give an index of structural changes in resistance vessels. Thirty-two subjects were separated into 4 groups: 8 with sustained hypertension, 8 with intermittent hypertension, 8 treated hypertensive subjects maintained at systolic pressures of less than 125 mm Hg with drugs for 5 years, and 8 normal subjects. Flow was measured by venous occlusion plethysmography after 10 minutes of ischemia, using a water-filled plethysmograph at 43°C. Arterial blood pressure was measured by the arm cuff method. Transmural pressure, calculated as mean arterial minus external pressure, was varied by imposing varying external hydrostatic pressures. Flow at a transmural pressure of 85 mm Hg was calculated for each subject from the least-mean-square plot of transmural pressure vs flow. Mean flow for normal subjects was 41 ml/100 ml/min and differed significantly from that for sustained hypertensive patients (30 ml/100 ml/min), treated hypertensive patients (33 ml/100 ml/min), and intermittent hypertensive patients (32 ml/100 ml/min) ($p < 0.05$). There was no overlap between sustained hypertensives and normal subjects, but half of the treated hypertensive patients were normal. Intermittent hypertensive patients usually showed evidence of pronounced arterial changes. Prolonged therapy appeared to reverse changes in some sustained hypertensives. This noninvasive method permits comparisons of hypertensive and normotensive subjects at equivalent transmural pressures.

(Am J Cardiol 1985;55:418–422)

Essential systemic hypertension in humans and spontaneous hypertension in the rat are characteristically associated with increased peripheral resistance.[1–3] This in turn may result from changes in smooth muscle tone or from structural changes in small blood vessels. The present study is concerned with whether hypertensive subjects show evidence of structural vascular changes when compared at equal transmural pressures, whether such changes can be detected in early stages of hypertension and whether they are reversible with treatment. Hypertensive and normal subjects were studied under conditions of maximal vasodilation wherein flow at a given driving pressure was considered to give an index of structural changes in resistant vessels.

Methods

Subjects: The subjects were 24 patients with uncomplicated sustained or intermittent essential hypertension and 9 normal subjects. The subjects were separated into 4 groups:

Group I (sustained hypertensives): Each subject showed blood pressure (BP) readings of at least 140/90 mm Hg in supine and erect postures on each visit. Six subjects were untreated and 2 were hypertensive despite treatment.

Group II (intermittent hypertensives): Subjects were untreated and showed BP levels that varied above and below 140/90 mm Hg.

Group III (optimally treated hypertensives): Before treatment, each subject had shown sustained hypertension during 4 to 6 visits (average BP for all subjects 155 ± 7/101 ± 4 mm Hg supine, and 156 ± 5/109 ± 3 mm Hg standing). Thereafter, each subject showed systolic BP readings that did not exceed 125 mm Hg on all visits during at least 5 years of treatment before study (average of 118 ± 2/80 ± 2 mm Hg supine, and 118 ± 1/86 ± 1 mm Hg standing).

Group IV (normal subjects): Each showed BP levels less than 125/80 mm Hg in supine and standing positions during each visit.

TABLE I Patient Characteristics

	Sustained Hypertensives Group I	Intermittent Hypertensives Group II	Treated Hypertensives Group III	Normal Subjects Group IV
BP (mm Hg)*				
Supine	154 ± 3/101 ± 3	138 ± 3/87 ± 2	118 ± 2/80 ± 2	110 ± 3/66 ± 2
Standing	156 ± 4/108 ± 2	134 ± 2/97 ± 2	108 ± 1/86 ± 1	108 ± 2/75 ± 1
Age (yr)	43 (33–52)	45 (28–54)	49 (37–61)	41 (27–50)
Race	6B/2W	4B/4W	3B/5W	2B/6W
Sex	3F/5M	2F/6M	2F/6M	2F/6M

* Average of 6 visits for groups I, II and IV and of all visits during at least 5 years for group III. Blood pressures (BP) before initiation of therapy in group III averaged 155 ± 7/101 ± 4 (supine) and 156 ± 5/109 ± 3 (standing) during 4 to 6 visits. BP values are mean ± standard error of the mean; age values are mean and range (years).

Assignments to various groups were based on BP recordings during 6 different visits over 4 to 6 weeks preceding experimental studies for groups I, II and IV and all BP recordings (at least 12 per subject) during at least 5 previous years of continual observations for group III. Patient characteristics and BP for each group before entering the study are shown in Table I. The various groups were reasonably matched, though not exactly, for age and sex. All subjects received no medication for at least a week before plethysmography.

Procedures: Studies were performed in a room maintained at a temperature of 22 to 26°C. BP was measured in 1 arm with a sphygmomanometer. Hand blood flow was measured in the other arm by venous occlusion plethysmography immediately after 10 minutes of arterial occlusion intended to produce maximal vasodilation. A water-filled plethysmograph was used as shown in Figure 1. The hand was enclosed in a loosely fitting thin rubber glove and placed in a rigid chamber, and maintained above heart level in all studies. The chamber was filled from a constant temperature bath maintained at 43°C; water in the chamber was exchanged with that in the bath for 3 minutes before each run. The plethysmograph chamber was connected by Tygon® tubing to a cylinder containing a float that displaced a linear motion transducer as the water level rose. The linear displacement was calibrated to measure volume changes by injecting known amounts of water into the chamber. The cylinder was placed on a platform that was raised or lowered on a pole to give varying levels of hydrostatic pressure in the chamber.

Before each run the veins of the hand were emptied by elevating the pressure in the chamber. Thereafter, the cuff on the forearm was abruptly filled with air and maintained at suprasystolic levels for 10 minutes to induce ischemia (Fig. 2). Flow during postischemic vasodilation was measured after

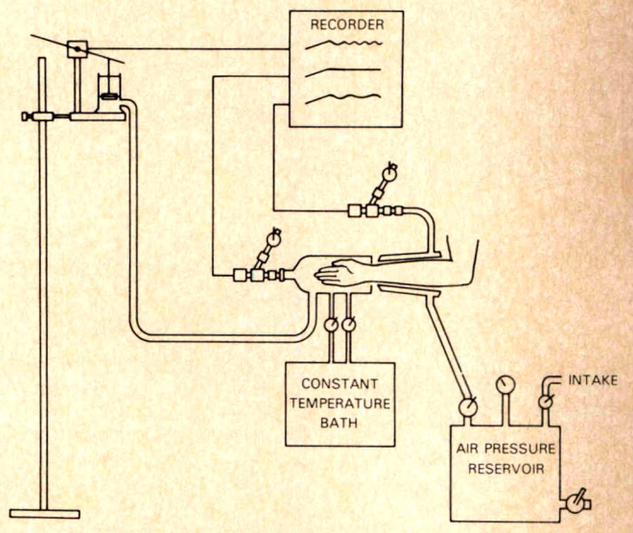

FIGURE 1. The experimental apparatus.

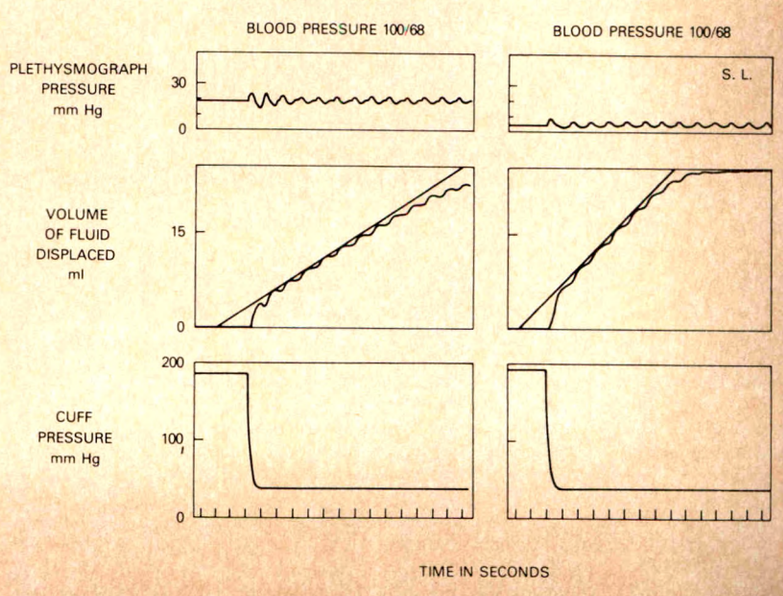

FIGURE 2. Curves of displacement of fluid from the plethysmograph after abrupt reduction of cuff pressure from occlusive levels. Studies are of the same subject (S.L.) at 2 plethysmograph pressures. The more rapid displacement of fluid with a lower external pressure in the plethysmograph reflected the greater hand flow accompanying a higher transmural pressure.

abruptly reducing the cuff pressure to between 40 and 60 mm Hg, which was higher than the chamber pressure but lower than the diastolic BP. Under these circumstances, the arterial inflow to the hand resumed in the absence of venous outflow, resulting in an increase in the volume of the hand. This in turn displaced fluid from the chamber. Hand blood flow (ml/s) was measured from the initial slope of the curve of volume displacement vs time. Such measurements were based on a line drawn tangent to 3 complexes (excluding the first complex which often included a cuff artifact) as shown in Figure 2.

In a typical study, the subjects underwent 6 to 8 runs separated by intervals of 3 minutes, during which the temperature in the chamber was equilibrated with the constant temperature bath. A series of different levels of chamber pressure (5 to 40 mm Hg) was imposed on the hand by varying the height of the meniscus in the cylinder above the chamber (Fig. 2). Chamber pressure and cuff pressure were recorded continuously by Statham gauges (P23Db). Measurements and decisions about suitability of runs were made by an observer blinded to the clinical status of the subject.

Blood flow increased in successive postischemic runs and stabilized by the third run. Because of this, the first 2 runs of a series of 6 to 8 runs were discarded and a curve of flow vs transmural pressure was computed for each subject using a least-mean-square plot of the remaining runs. The predicted flow for a transmural pressure of 85 mm Hg was obtained from this curve for each subject.

An additional normal subject underwent studies to determine whether flow during postischemic vasodilation was altered by the reflex sympathetic discharge resulting from placing the contralateral hand in ice water for up to 3 minutes. The findings are shown in Figure 3. Flow during the hyperemic state was unchanged when the contralateral hand was placed in ice water and followed the linear relation of flow vs transmural pressure observed when the contralateral hand was at 25°C. In the absence of hyperemia, flow decreased markedly after immersion of the contralateral hand in ice water, despite increased BP.

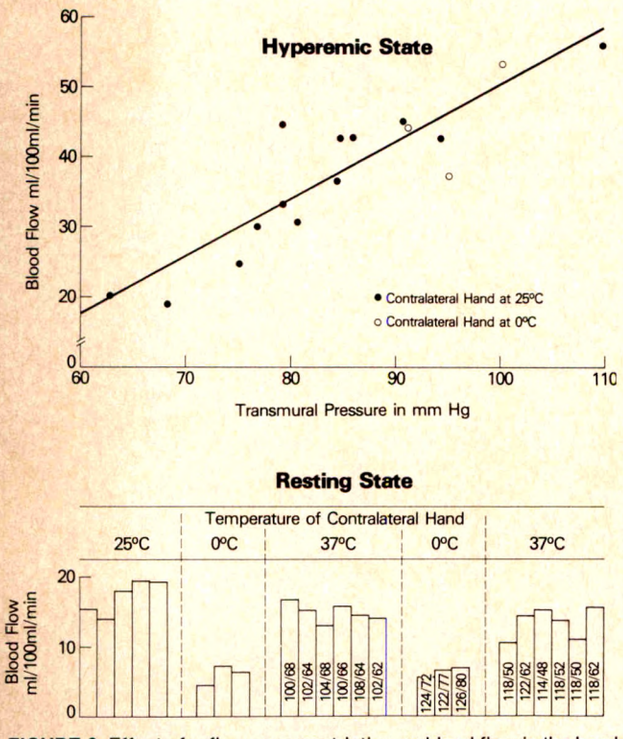

FIGURE 3. Effect of reflex vasoconstriction on blood flow in the hand during and in the absence of postischemic hyperemia. **Top,** during the hyperemic state the relation of blood flow and the transmural pressure was similar when the contralateral hand was at room temperature (**solid circles**) and when it was immersed in ice water (**open circles**). **Bottom,** in the absence of postischemic hyperemia, blood flow decreased strikingly in response to immersing the contralateral hand in ice water despite higher systemic blood pressures.

Theoretical considerations and data analysis: The hemodynamics of blood vessels subjected to external pressure is governed by the Starling resistor, or waterfall, phenomenon[4] provided that the external pressure (P_θ) lies between inflow pressure (P) and the outflow pressure (P_0). In this model, flow (Q) is independent of the exit pressure. Flow is then governed by the driving pressure, which in this case is equal to the transmural pressure, i.e., inflow pressure (P) minus external pressure (P_θ) and is not influenced by variations of P_0.[4,5]

In this study, the mean value of the lumen pressure (P) at the arterial end was determined using a sphygomanometer on the opposite arm and calculated as P = diastolic blood pressure + 1/3 pulse pressure. With the hand in the plethysmograph chamber, P_θ was considered to be the chamber pressure as measured by a Statham gauge. P_0, the pressure in the veins outside of the chamber, was not measured; however, it was assumed to be low in the initial filling phase.

The transmural pressure at the arterial end was calculated as[6]:

$$TMP = P - P_\theta.$$

The resistance (R) of the vascular bed within the chamber is given as:

$$R \simeq \frac{P - P_\theta}{Q} \simeq \frac{TMP}{Q}.$$

In Figure 4, flow is plotted against transmural pressure. The slope of this curve gives the reciprocal of resistance (i.e., conductance) of the vascular bed of the hand.

Results

Figure 4 is a plot of hand blood flow vs transmural pressure of individual runs of normal subjects (Group IV) and patients with sustained hypertension (Group I). The regression lines for each group differed significantly in position ($p < 0.001$), but not in slope ($p < 0.2$). The flow increased with an increase in transmural pressure in both groups but at a given value of transmural pressure, flow was higher in the normal subjects.

Figure 5 shows the hand blood flow at 85 mm Hg transmural pressure for each subject. The mean and standard error of the mean for each group are also shown. Flow in this case is inversely proportional to vascular resistance because the driving pressure, equal to transmural pressure, is constant. Mean flow of normal subjects differed significantly from mean flow of each of the hypertensive groups ($p < 0.05$) when analyzed by analysis of variance. Analysis by a nonparametric method (Kruskal-Wallis statistic with Miller approximation) similarly showed a significant difference between normal subjects and patients with sustained or intermittant hypertension ($p < 0.05$), but significance was not achieved for the comparison of normal subjects and treated hypertensive patients.

Values of computed flow for individual untreated sustained hypertensive patients did not overlap values

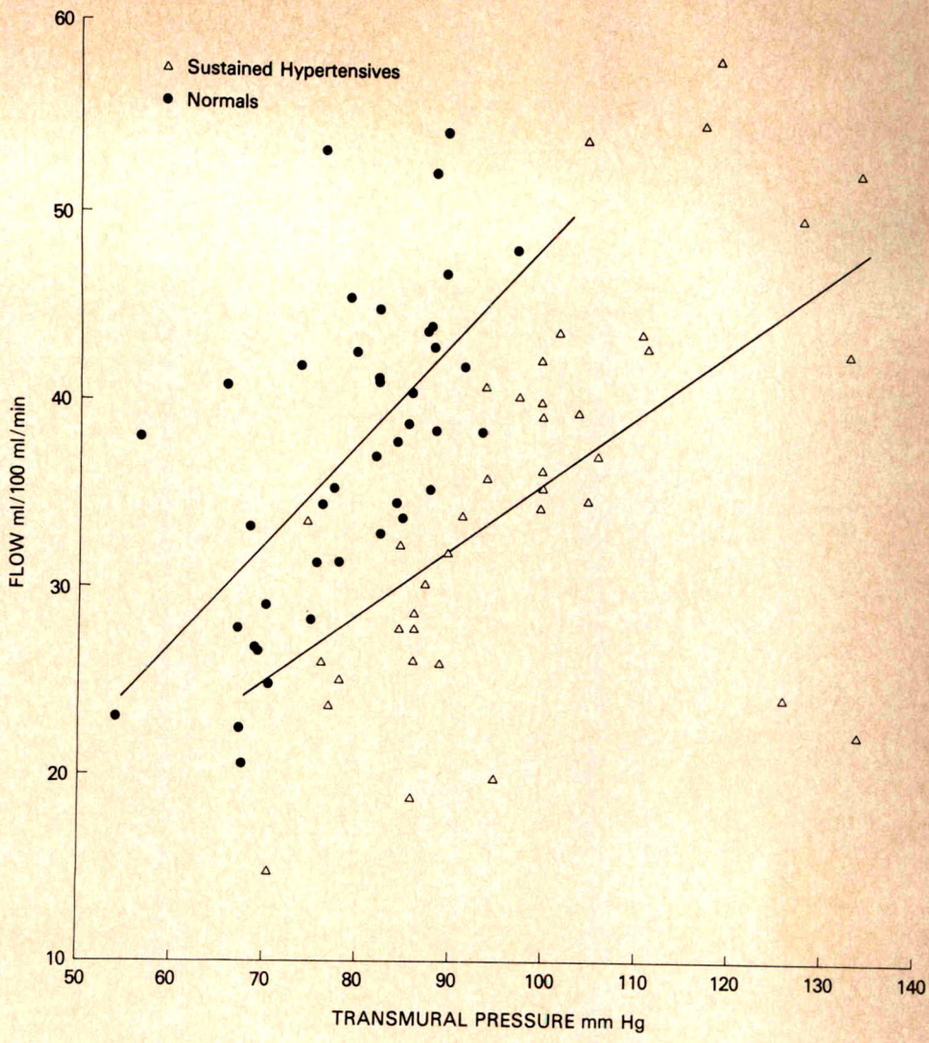

FIGURE 4. Relation of hand blood flow and transmural pressure during all studies of untreated sustained hypertensives and normal subjects. Regression lines are plotted for the 2 groups.

for normal subjects, whereas half of treated hypertensive patients resembled normal subjects. Analysis by Fisher's exact test showed significant differences between the treated and sustained hypertensive groups ($p < 0.03$). There was no obvious relation between the types of drugs received (diuretics, propranolol, methyldopa or hydralazine) and failure of flow to reach control levels.

The only intermittent hypertensive patient with high hand blood flow in Figure 5 clinically appeared to have a hyperdynamic circulation with tachycardia.

Discussion

The present study shows that hand blood flow and vascular conductance of hypertensive subjects during postischemic vasodilation was less than that of normal subjects. Similar results have been obtained by others in the forearm[1,3] and hand.[7]

Based on observations of others using infusions of norepinephrine[1,3] or phenylephrine[8] or using sym-

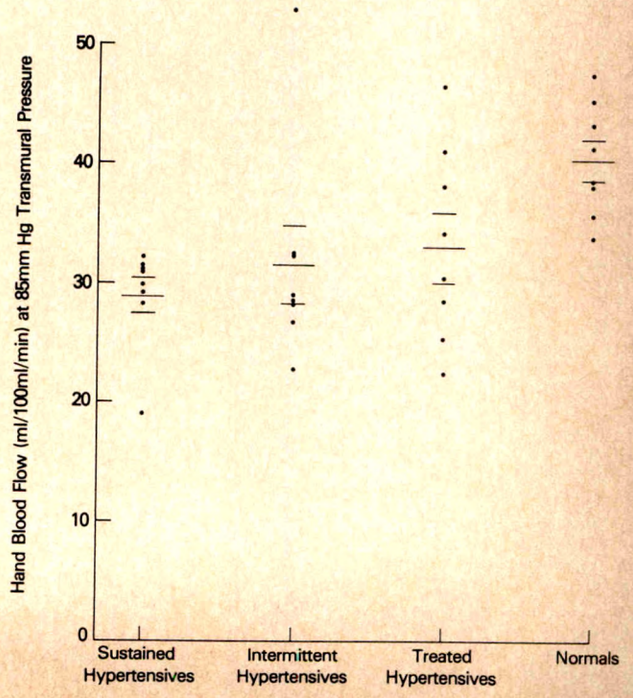

FIGURE 5. Computed hand blood flow at a transmural pressure of 85 mm Hg for each subject in the 4 groups. Mean flow and standard error of the mean for each group are also plotted.

pathectomized subjects,[9] it is reasonable to assume that the postischemic blood flow during maximal vasodilation is relatively free from the influence of sympathetic nervous tone. In the present study we could not evoke reflex vasoconstrictive responses to a cold stimulus during postischemic vasodilation, whereas pronounced responses occurred during control observations in the same subject (Fig. 3).

Assuming an absence of sympathetic neurohumoral or other vasoconstrictor influences during postischemic vasodilation, the caliber of the blood vessel would be governed by the transmural pressure of the vessel and structural changes in the vessel wall. Since comparisons between various groups were made at comparable values of transmural pressure,[6] the results of the present study, i.e., a decrease in hand blood flow and an increase in vascular resistance in hypertensive subjects (Fig. 4 and 5), suggest structural changes in the small blood vessels of the hand. Our findings in the treated hypertensive patients suggest that such structural changes may be reversed by prolonged therapy. Similar results were obtained by Sivertsson and Hanson[10] in patients restudied after 5 years of therapy.

The method was sensitive enough to pick up early changes in blood vessels of intermittent hypertensives. Similarly, Takeshita et al[8,11] showed a lower vasodilator capacity of forearm resistance vessels in borderline hypertensive patients and normotensive subjects with a family history of hypertension. Thus, this simple noninvasive method may be useful in following the adaptation of blood vessels in the early states of hypertension and during various therapies.

Acknowledgment: We thank Joan Folio and Gary Friedlander for technical assistance and Dr. Harry Keiser for his support throughout this research. Thanks are also due to Claudette Williams for typing the manuscript.

For **every** professional with an interest in Exercise and the Heart.

EXERCISE in Cardiovascular Health and Disease

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

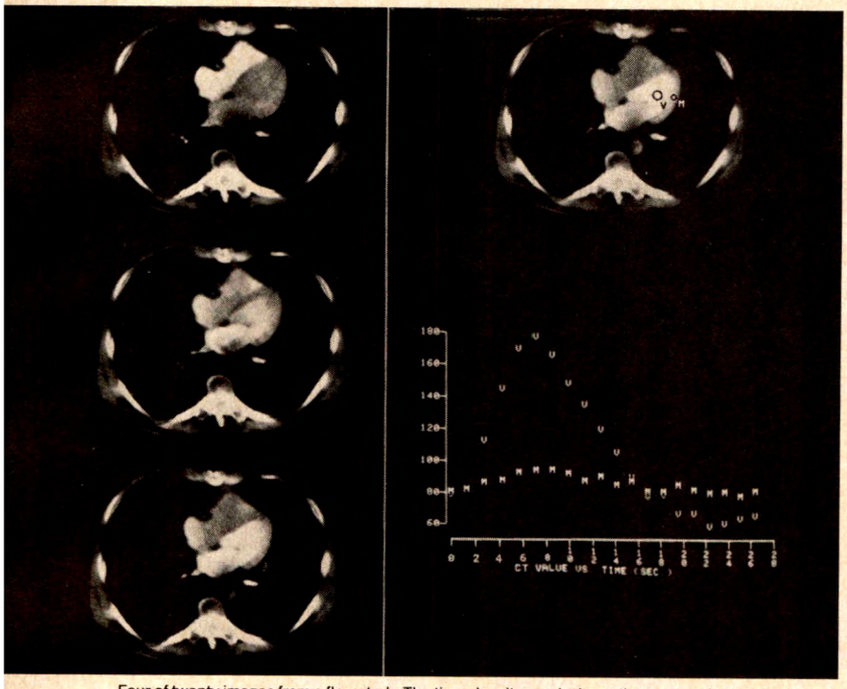
What if you could assess his coronary risk before catheterization?

Introducing Cine-CT™



Four of twenty images from a flow study. The time-density graph shows the progressive opacification of selected regions of interest from an intravenous bolus of contrast.

Nine months ago this patient nderwent coronary bypass surgery. ack at work, he is now experiencing fort chest pain. Should he undergo rther arteriography?

What if you could do a single, uick, non-invasive outpatient study at rest and under stress—that gave ou not only good anatomical detail ut functional data and blood flow easurements?

At a scan speed 30 times faster an conventional CT, the new natron Cine-CT scanner demonrates the transit of peripherally jected contrast material as it flows rough the cardiac chambers and rfuses the myocardium. It gives you highly specific and sensitive estimaon of wall motion, absolute myordial blood flow, and graft flow id patency.

984 Imatron Inc.

What if you could measure the size of her infarction?

This 42-year-old lawyer was hospitalized to rule out a possible myocardial infarction. With nonspecific ECG findings and slightly elevated enzyme levels, what is the prognosis?

With the new Cine-CT scanner, you could document the location and size of her myocardial infarction and determine that her remaining perfusion is normal.

What if you could determine whether his myocardial perfusion is normal under stress?

Previously healthy, this 37-year-old engineer recently developed atypical chest pain. His rest ECG is normal, but a treadmill test was equivocal for ischemia, and his father died prematurely of acute myocardial infarction at age 44.

With Cine-CT, you could non-invasively assess his myocardial perfusion at rest, under stress and during pain. You could also study his wall and chamber dynamics under the same conditions.

Because of its speed—50 msec per scan, 17 scans per second—and multislice capability, Cine-CT greatly expands the diagnostic potential of computed tomography. With it you can assess wall thickness and motion, left and right ventricular chamber volumes and mass, myocardial perfusion and valvular insufficiency.

To learn how you can use this exciting new technology to benefit your patients, contact your regional sales representative to schedule a showing of our videotapes. Imatron Inc., 389 Oyster Point Blvd., South San Francisco, CA 94080, (415) 583-9964.

a on file, CIBA Pharmaceutical Co.

Transderm-Nitro

(nitroglycerin)
Transdermal Therapeutic System

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)*

INDICATIONS AND USAGE
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response. The Transderm-Nitro 2.5 system is useful principally for decreasing the dosage gradually, though it may provide adequate therapy for some patients when used alone.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

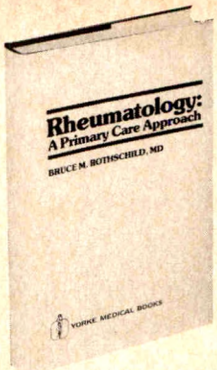
The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind



Rheumatology
A Primary Care Approach

Written by:
Bruce M. Rothschild, MD
Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V.A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8, $42.50, 430 pp., illus., 1982.

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Abbreviated Table of Contents

Section 1 **Investigative Techniques**
Section 2 **Patterns**
Section 3 **Management**

"This compact, well-designed and generally informative volume is a useful reference for the management of rheumatic disease by physicians who deliver primary care. The family physician will undoubtedly use this frequently as a reference."
Charles M. Plotz, MD American Family Physician

"This book is a good primer for students, residents, and health professionals who would like a glimpse into rheumatology. It can be recommended for all but the specialist (but perhaps the specialist should read it, too, to see what those he is training are learning)."
George E. Ehrlich, MD JAMA September '83

This is a superb text by a sensitive, concerned, organized author of international repute . . . Each chapter is well outlined, concise, practical, and has a current and appropriate bibliography at the end . . . a skillfully structured text which is a quality contribution . . . a very readable text."
John A. Feagin, Jr., MD Military Medicine March '83

Initial therapy should start on the right course.

ypertensive patients

Minipress® for initial therapy
(prazosin HCl)

- Is effective when used alone
- Does not cause a significant incidence of sexual impotence, although it has been reported[1]
- Does not adversely affect blood lipids*[2]
- Does not lower heart rate, cardiac output or work capacity[3]
- Does not induce potassium wasting[1]
- Most common side effects with Minipress, generally mild and transient, are dizziness, headache, drowsiness, palpitations, and nausea. Syncope (sudden loss of consciousness) has been reported in about 0.15% of patients at the recommended initial dose of 1 mg.

*Minipress is not indicated for the treatment of hyperlipidemia.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

for Initial Therapy in Hypertension

Please see Minipress brief summary on following page

© 1983, Pfizer Inc.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

Brief Summary
MINIPRESS® (prazosin hydrochloride) Capsules ***For Oral Use***

INDICATIONS: MINIPRESS (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS: Minipress may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120–160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS. The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution. (See DOSAGE AND ADMINISTRATION.) Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsule of MINIPRESS. The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS in pregnancy has not been established. MINIPRESS is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See WARNINGS.)

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

OVERDOSAGE: Accidental ingestion of at least 50 mg of MINIPRESS in a two year old child resulted in profound drowsiness and depressed reflexes. No decrease in blood pressure was noted. Recovery was uneventful.

Should overdosage lead to hypotension, support of the cardiovascular system is of first importance. Restoration of blood pressure and normalization of heart rate may be accomplished by keeping the patient in the supine position. If this measure is inadequate, shock should first be treated with volume expanders. If necessary, vasopressors should then be used. Renal function should be monitored and supported as needed. Laboratory data indicate MINIPRESS is not dialysable because it is protein bound.

TOXICOLOGY: Testicular changes, necrosis and atrophy have occurred at 25 mg/kg/day (60 times the usual maximum recommended dose of 20 mg per day in humans) in long term (one year or more) studies in rats and dogs. No testicular changes were seen in rats or dogs at the 10 mg/kg/day level (24 times the usual maximum recommended dose of 20 mg per day in humans). In view of the testicular changes observed in animals, 105 patients on long term MINIPRESS (prazosin hydrochloride) therapy were monitored for 17-ketosteroid excretion and no changes indicating a drug effect were observed. In addition, 27 males on MINIPRESS (prazosin hydrochloride) alone for up to 51 months did not demonstrate changes in sperm morphology suggestive of drug effect.

HOW SUPPLIED: MINIPRESS is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

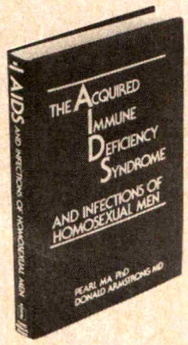
AIDS
An important new book on today's most virulent epidemic



From the Publishers of The American Journal of Medicine, The American Journal of Surgery, and Cutis

Acquire Immune Deficiency Syndrome (AIDS) and Infections of Homosexual Men

edited by **Pearl Ma, PhD,** and **Donald Armstrong, MD** with a foreword by **David J. Sencer, MD,** *Commissioner of Health, New York City; formerly Director, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services*
0-914316-38-9, 442 pages, illus., 1984, $39.50

The first scientific presentation to review all the facts in full

AIDS has become one of the most publicized diseases in modern times. It has produced fear and confusion in the general public and presented a formidable challenge to the medical community. Physicians and scientists have begun work on managing this epidemic, disease control centers continue to search for answers, and the federal government has declared AIDS the number one health priority of the nation. Understanding this disease demands cooperation between many different medical specialties, and papers on this subject have been published in many diverse journals not regularly read by individual specialists. Now, for the first time, two highly distinguished medical experts, Drs. Pearl Ma and Donald Armstrong, have coordinated in one easily accessible volume the complete range of interdisciplinary approaches to this complex disease, with contributions by the most eminent researchers and physicians in disease control and hospital teaching centers throughout the country. Comprehensive coverage is given to the entire spectrum of sexually transmitted diseases, and an additional section on diagnostic perspectives offers never before published material on why this syndrome occurs primarily among homosexual men. For any physician or other health care professional interested in the prevention and cure of this modern epidemic, this book is an indispensable guide to recognizing and treating AIDS and other sexually transmitted diseases.

Table of Contents

• PART I SEXUALLY TRANSMITTED DISEASES — NONDIARRHEAL • PART 2 SEXUALLY TRANSMITTED DISEASES — DIARRHEAL • PART 3 OTHER SEXUALLY TRANSMITTED DISEASES • PART 4 INFECTIOUS AND NEOPLASTIC COMPLICATIONS OF AIDS • PART 5 IMMUNOLOGICAL EVALUATION METHODS AND CONTROLS • PART 6 DIAGNOSTIC PERSPECTIVE

Clinical Echocardiography

Hemodynamic and Pathological Correlations

by José Missri, MD

0-914316-41-9, 282 pages, 173 illus., Oct. '84, $45.00

Dr. Missri has produced a unique contribution to the further understanding and application of Doppler echocardiography in the clinical practice of medicine. This book provides the reader with ready access to a body of knowledge so logically and clearly presented that its practical utility is undeniable. Enhanced by 139 halftones, 16 line drawings and 18 tables, the information contained within its concise 282 pages is easily absorbed. And the 315 references cited not only support the material presented but serve as an excellent guide to anyone interested in further in-depth reading.

(nitroglycerin tablets, USP)

Before prescribing, please see full prescribing information.
A Brief Summary follows:

INDICATIONS
Nitroglycerin is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain):
N 0071-0568-24—Bottle of 100 tablets;
N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain):
N 0071-0569-24—Bottle of 100 tablets;
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain):
N 0071-0570-24—Bottle of 100 tablets;
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain):
N 0071-0571-24—Bottle of 100 tablets;
N 0071-0571-13—Convenience Package.

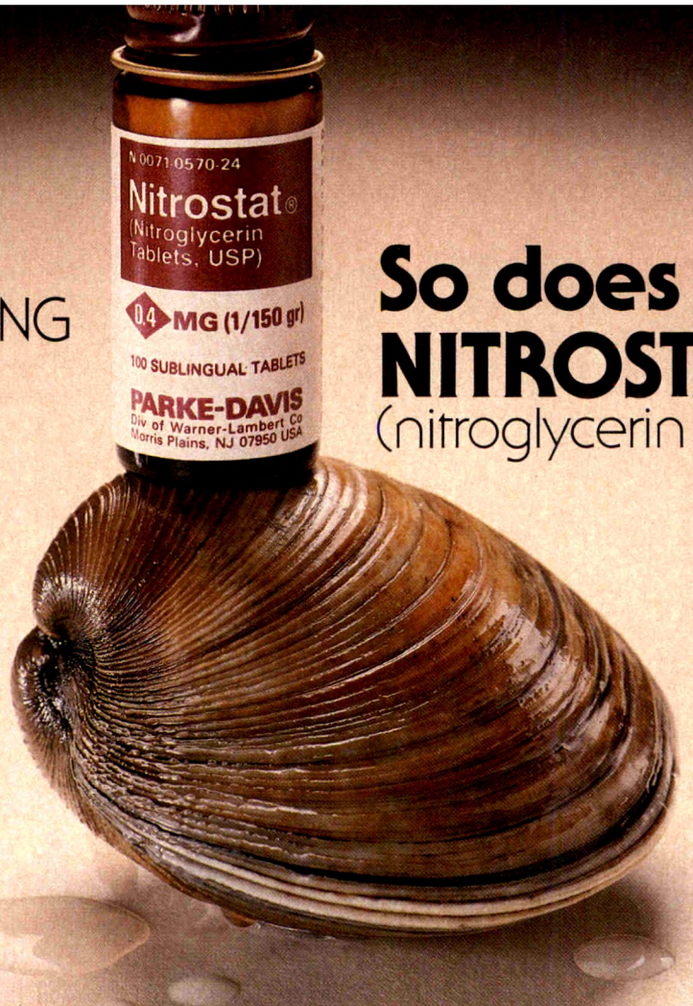
NATURE
HAS A WAY
OF PROTECTING
ITS OWN.



So does NITROSTAT®
(nitroglycerin tablets, USP)

Just by the way it's made, NITROSTAT, too, has built-in protection—protection against loss of nitroglycerin. In fact, NITROSTAT is more stable than conventional nitroglycerin tablets under all conditions of temperature and humidity tested.

But that's not all. Average assay still shows better than 100% of label claim for at least 60 months after manufacture of NITROSTAT. Because of this stability NITROSTAT has a five-year expiration date.*

What's more, only NITROSTAT Tablets are available in convenient packages of 4 x 25 tablets. So emergency angina relief can be ready when needed in four different locations. "Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug among the organic nitrates that can be given sublingually."[1] NITROSTAT...useful alone or as concomitant therapy with long-acting nitrates or propranolol.

*Five-year expiration date when stored at recommended storage conditions in an unopened bottle. Data on file, Medical Affairs Dept, Parke-Davis

Vascular Hemodynamic Impedance in Congestive Heart Failure

STANLEY M. FINKELSTEIN, PhD, JAY N. COHN, MD, V. ROSS COLLINS, MD, PETER F. CARLYLE, BS, and WENDA J. SHELLEY, BA

The objective of this study was to determine whether pulse-contour analysis could provide a measure of the differences in peripheral vascular state between patients with congestive heart failure (CHF) and healthy persons. Vascular hemodynamic impedance parameters were determined from brachial artery pressure waveforms recorded in 14 patients with CHF, aged 20 to 55 years (mean 36 ± 12) and in 7 healthy control subjects, aged 22 to 55 years (mean 33 ± 12). Cardiac output, heart sounds and electrocardiogram were also monitored. Cardiac output was 32% lower ($p < 0.01$) and heart rate was 43% higher ($p < 0.001$) in the CHF group than in the control group. The mean arterial pressure did not differ between groups. Systemic vascular resistance was 47% higher ($p < 0.05$) and distal vascular compliance 73% lower ($p < 0.001$) in the CHF group than in control group. Proximal vascular compliance was unchanged. These studies suggest that distal compliance assessed from pulse-contour analysis is a more sensitive and specific index than systemic vascular resistance to the vascular changes in CHF.

(Am J Cardiol 1985;55:423–427)

The characteristics of the peripheral vasculature are important in determining arterial pressure and left ventricular performance in patients with congestive heart failure (CHF). Peripheral vascular resistance is the parameter most frequently used to describe the peripheral vascular bed. However, recent studies suggest that frequency-dependent vascular impedance may be a more sensitive indicator of disease and therapeutic response.[1–11] The determination of this impedance requires Fourier analysis of simultaneously recorded pressure and blood flow waveforms, generally measured at the ascending aorta.

An alternative to this direct impedance measurement uses the peripheral arterial pressure pulse contour to derive vascular impedance properties.[12–15] This method requires only an arterial puncture to obtain a peripheral pressure signal, and thus offers the potential of practical clinical use. The resulting parameters are interpreted in terms of a Windkessel-type model of the vasculature and provide derived values for vascular compliance and resistance. In 1967, Goldwyn and Watt[12] proposed using such a model for interpreting the changes in arterial pressure waveshape in response to drug or disease intervention, and in 1976, Watt and Burrus[13] used a modified Windkessel for determining vascular resistance and compliance in hypertensive and healthy control subjects. These studies demonstrated that peripheral vascular resistance is increased and vascular compliance decreased in hypertensive patients.

More recently, Zobel et al[16] reported that the pulse-contour–derived distal compliance was a sensitive and drug-dependent indicator of a vasodilator response in dogs, and that this method was more sensitive than characteristic impedance or static resistance in monitoring vasodilator drug response.[17]

In the current study, the pulse-contour-Windkessel method has been applied to patients with CHF to determine if differences in vascular properties in these patients can be detected by such a method of analysis.

Methods

Studies were performed on 14 patients with CHF and 7 healthy control subjects. The CHF group consisted of 9 men

and 5 women, 20 to 55 years (mean ± standard deviation 36 ± 12). The diagnosis of CHF was based on a history of fatigue, dyspnea, orthopnea, a third heart sound, pulmonary rales, jugular venous distention or pulmonary vascular congestion and radiologic or echocardiographic evidence of left ventricular dilatation. Pulmonary capillary wedge pressure ranged from 16 to 32 mm Hg, right atrial pressure from 2 to 22 mm Hg, and ejection fraction by radionuclide or contrast angiography from 10 to 33%. All subjects were in normal sinus rhythm at the time of the study. Heart failure was the result of coronary heart disease in 6 patients and idiopathic cardiomyopathy in 8 patients. All vasodilator drugs were withdrawn at least 72 hours before the study; digitalis and diuretic drugs were withheld for at least 12 hours before the study. All patients were clinically stable at the time of the study. The healthy control group consisted of 3 men and 4 women, aged 22 to 55 years (mean 33 ± 12). All study participants gave written, informed consent.

Pressure was recorded from the brachial artery using an 18-gauge, 2-inch Teflon® catheter connected to a Statham P23Db pressure transducer. This catheter-transducer system has an undamped natural frequency higher than 25 Hz and a damping coefficient less than 0.5, as measured by balloon pop in this laboratory. This frequency response is adequate for the pulse-contour technique.[15] Aortic valve closure was determined from heart sounds from the upper left sternal border. The beginning of the second heart sound indicated the onset of diastole, and the upstroke of the brachial artery pulse was used to mark the end of diastole. A thermodilution balloon flotation catheter was positioned in the pulmonary artery after percutaneous insertion into a brachial vein in the patients with CHF. Cardiac output was determined in triplicate by thermodilution. In normal subjects, cardiac output was measured by the thoracic impedance technique using the Minnesota Impedance Cardiograph model 30413.[18,19]

Waveforms were recorded for 30 seconds for each subject in a supine position, after at least 60 minutes supine rest after catheter positioning. All hemodynamic data were recorded on both paper and magnetic tape. Data were digitized using a 12-bit analog-to-digital converter, operating at 200 samples per second per channel. Digitized data were saved on disk for subsequent beat marking, signal processing and pulse-contour analysis. The onset and end of diastole for the brachial artery pressure waveform were marked on 6 consecutive beats and the modified Gauss-Newton parameter-estimating algorithm was run on each marked beat.[16] Each group of 6 consecutive beats was selected manually from each 30-second record, choosing the group with the most noise-free pressure and phonocardiogram signals as viewed by the operator. The diastolic waveform for each beat can be represented most generally as a third-order function:

$$P(t) = A_1 e^{-A_2 t} + A_3 e^{-A_4 t} \cos(A_5 t + A_6)$$

and the parameter-estimating algorithm calculated the optimal values for the Ai (i = 1 . . . 6), so that the estimated function fit the observed data with a minimum least squares error. These Ai coefficients, mean pressure and cardiac output were then used to determine the circuit elements (compliance, inertance and resistance) in a modified Windkessel model of the vasculature (Fig. 1), in which the measured brachial arterial pressure was taken as $P_2(t)$. Heart rate, pulse velocity and wave reflections do not figure directly in the determination of the circuit parameters. The results for each 6 consecutive beats were averaged, and the mean values were used in the statistical data analysis.

Regression analysis was used to determine relations between hemodynamic variables and impedance parameters within each group. Differences between the control and patient groups were determined using the unpaired *t* test. All data are presented as mean ± standard deviation.

Results

An example of the brachial artery pressure curves observed in the control and CHF groups is shown in Figure 2. The diastolic wave is the portion of the waveform studied in the pulse-contour procedure. The parameter-estimating algorithm was run on 6 consecutive beats for each subject and in all cases converged to a minimal error between estimated and observed brachial artery pressure of less than 2 mm Hg, over a pressure range of approximately 60 to 100 mm Hg. Coefficients of variation for distal compliance C2 over the 6 beats in each subject grouping ranged from 3 to 14%.

The data are summarized in Table I, which lists hemodynamic variables, pressure-contour parameters (A2, A4 and A5) and the vascular impedance parameters derived from the modified Windkessel circuit analysis. As expected, the major hemodynamic differences between the control and patient groups were a 49% lower

TABLE I Hemodynamic Measurements, Pulse-Contour–Derived Parameters, and Windkessel Model Impedance Parameters for the Arterial Vasculature

Variables & Parameters	Healthy Controls (n = 7)	Congestive Heart Failure (n = 14)
Hemodynamic measurements		
MAP (mm Hg)	83 ± 10.8	75 ± 8.6
HR (beats/min)	67 ± 10.8	96 ± 17.6*
CO (liters/min)	6.10 ± 1.1	4.13 ± 1.32†
SV (ml/beat)	93.0 ± 21.2	47.3 ± 20.0*
Pressure contour parameters		
A2 (s^{-1})	0.67 ± 0.16	0.66 ± 0.26
A4 (s^{-1})	5.51 ± 5.48	15.66 ± 7.76†
A5 (s^{-1})	22.50 ± 8.65	22.21 ± 12.29
Impedance parameters		
R (dynes s cm^{-5})	1113 ± 183	1634 ± 587‡
C1 (ml/mm Hg)	1.83 ± 0.48	1.85 ± 1.26
C2 (ml/mm Hg)	0.15 ± 0.07	0.04 ± 0.03*
L (mm Hg/ml/s^2)	0.017 ± 0.005	0.062 ± 0.061

* $p < 0.001$; † $p < 0.01$; ‡ $p < 0.05$.
Data are expressed as mean ± standard deviation.
C1 = proximal compliance; C2 = distal compliance; CO = cardiac output; HR = heart rate; L = inertance; MAP = mean arterial pressure; R = peripheral resistance; SV = stroke volume.

stroke volume in heart failure ($p < 0.001$), a 43% faster heart rate ($p < 0.001$) and a 32% lower cardiac output ($p < 0.01$). Mean arterial pressure did not differ signficantly between the 2 groups. Systemic vascular resistance (SVR) in patients with CHF was increased by 47% ($p < 0.05$). Proximal compliance (C1), describing the elastic storage capability of the large arteries, is at least an order of magnitude larger than distal compliance (C2), which represents the elastic storage ability of the midsize arteries down to the arteriolar level. There was no significant difference in proximal compliance between the study groups. Distal compliance, however, was reduced by 73% in patients with CHF ($p < 0.001$). Inertance (L) was increased in heart failure, but because of the larger variability within each group these differences were not significant.

Six parameters are determined by the parameter-estimating algorithm that characterize the pulse-contour waveform. Three of these (A1, A3 and A6) are dependent on system initial conditions, and are not contributory in determining impedance properties of resistance, compliance and inertance. The 3 Ai parameters (A2, A4 and A5) listed in Table I are related to system structure and describe diastolic waveform oscillations and the exponential decay envelopes for these oscillations. Of these, only A4 was significantly different between the healthy control and CHF groups (189% higher in the CHF group, $p < 0.01$).

The age ranges were closely matched. Distal compliance and age were weakly correlated for the total population ($r = -0.44$) and for the CHF group ($r = -0.44$), as were SVR and age ($r = +0.41$ for the total population and +0.46 for the CHF group). Distal compliance was weakly correlated with cardiac output ($r = 0.56$) and heart rate ($r = -0.6$) and was not correlated with mean pressure. Multiple linear regression also failed to uncover any additional significant relations between vascular compliance and linear combinations of these hemodynamic variables. However, a strong correlation was seen between SVR and cardiac output ($r = -0.87$) in the CHF group. Resistance and distal compliance were uncorrelated in the CHF group.

Discussion

In previous animal and clinical studies we have modified and implemented the pulse-contour method of Goldwyn and Watt[12] and Watt and Burrus[13] and have shown that the Windkessel compliance parameters are more sensitive than either SVR or characteristic impedance as indicators of the vascular response to vasodilators.[16,17] Although the exact location of the vascular components cannot be determined from the model, because each element of the model is a composite functional representation, the model apparently can provide insight into the overall behavior of the vasculature.

Simon et al[14] reported a reduced compliance in hypertensive patients using a first-order Windkessel model that does not permit quantitative separation between large and small artery effects. Watt and Burrus,[13] using a third-order Windkessel model, found significant reduction in distal compliance in hypertensive subjects.[13] In the present study, proximal compliance was 1.83 and 1.85 ml/mm Hg and distal compliance was 0.15 and 0.04 ml/mm Hg ($p < 0.001$) for the control and CHF groups. These data agree with the Watt and Burrus results, and the sums of the proximal and distal compliances closely approximate the total compliance values reported by Simon. These data suggest that a reduction in distal vascular compliance is characteristic of heart failure, as well as of hypertension, and that this measurement may provide more insight into the site of vascular changes in these diseases than the simple calculation of SVR. A complete overlap in SVR between the normal subjects and patients with CHF was noted in the present study, whereas distal compliance values were quite discriminatory, as seen in the C2-R loci of Figure 3 and the scatterplots of Figure 4. One could speculate on the use of these vascular properties in discriminating between health and disease, particularly if such changes were to evolve early in the disease progression. For example, a C2 threshold value of 0.07 ml/mm Hg will clearly distinguish between the 2 groups. Control subjects have a relatively small range

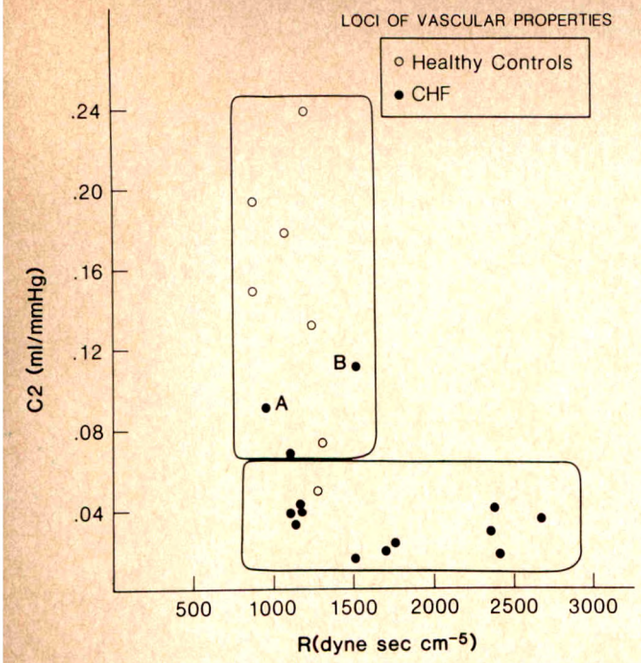

FIGURE 3. Loci of vascular distal compliance (C2) and peripheral resistance (R) for all subjects in the control group (n = 7) and the congestive heart failure (CHF) group (n = 14).

of resistance and a large range of distal compliance, whereas patients with CHF have the opposite pattern. Furthermore, the CHF subjects marked A and B in Figure 3 that fall within the control group locus had stroke volumes of 82 and 80 ml/beat, respectively, implying less severe heart failure. Thus the continuing movement of a subject's C2-R locus might provide a map of disease progression. Such a possibility must be tested in a prospective study to confirm its potential usefulness.

The correlation between the vascular parameters and cardiac output can be considered as a marker of the disease process rather than as an alternative indirect measure of cardiac output, since reports in the literature[13,14] and preliminary studies in this laboratory have also found significant changes in vascular compliance and resistance in hypertensive patients whose cardiac outputs are unchanged from that in control subjects but whose mean pressures are significantly elevated. That distal compliance and SVR are 2 independent properties of the vascular impedance load is further demonstrated in the compliance-resistance plot in Figure 3, showing the distinct loci for these vascular components in both the heart failure and control groups.

Pressure-contour parameter A4 changes significantly with heart failure and could be a potential marker for following vascular changes in heart failure (Table I). Because A4 describes the damping of the diastolic oscillation, the data suggest that patients with CHF have a more highly damped vascular system than normal subjects.

Vascular impedance by Fourier analysis has been reported extensively for the past 20 years in both animals and humans.[20–23] Pepine et al[4] reported that input resistance and characteristic impedance are significantly higher in CHF patients than in normal subjects, and suggested that the stiffer aorta might have significant influence on the pulsatile function of the failing left ventricle. These investigators also found that sodium nitroprusside lowered characteristic impedance.[5] In

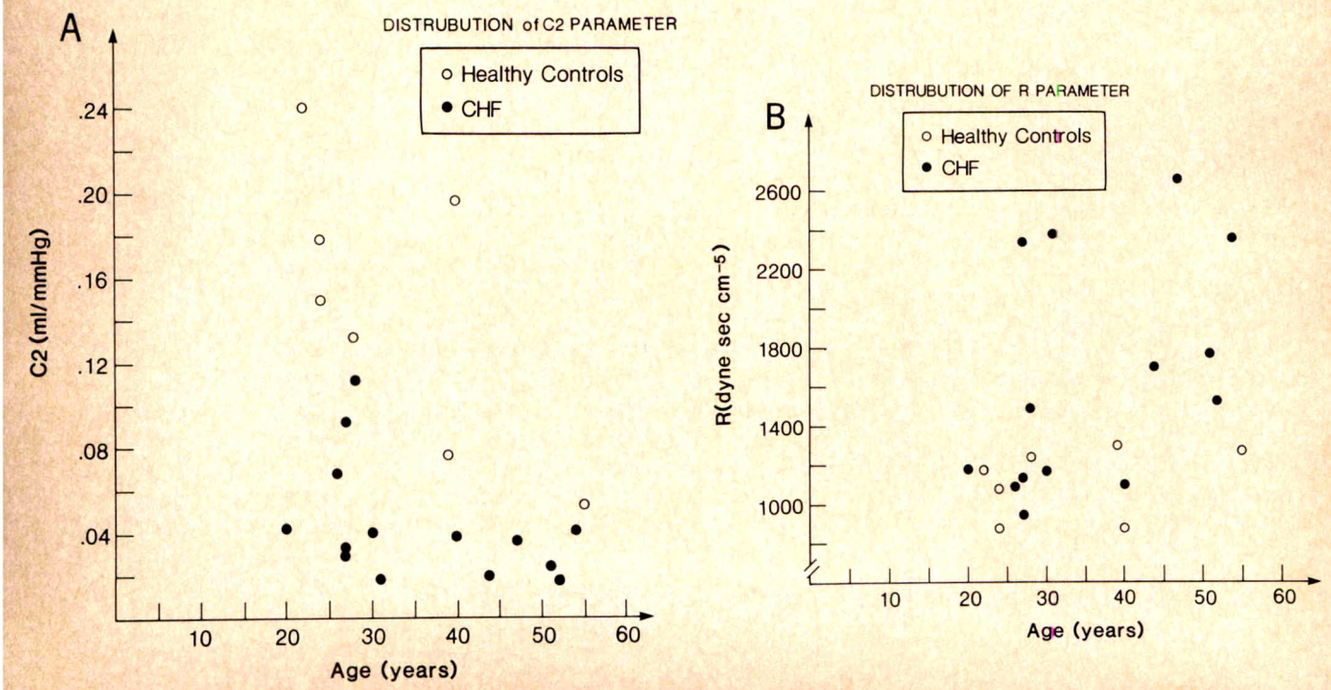

FIGURE 4. Scatterplots showing the distribution of vascular impedance properties with subject age for all subjects in the control and congestive heart failure (CHF) groups. **A**, distal compliance (C2) vs age; **B**, peripheral resistance (R) vs age.

contrast, Gundel et al[8] reported that characteristic impedance was essentially unchanged after nitroprusside. Yin et al[10] reported lower values for characteristic impedance at baseline than was reported by Pepine for a similar patient group, and like Gundel, did not find any change in response to nitroprusside. The value reported by Yin in heart failure (79 dynes s cm^{-5}) was actually lower than the value in normal subjects reported from the Pepine study (89 dynes s cm^{-5}).

Characteristic impedance is calculated by averaging impedance moduli for the higher-frequency components of the impedance spectrum. There is no standard for determining the frequency range used in this calculation, although frequencies from 2 to 12 Hz are frequently used. Because the impedance moduli at each of these frequencies may be highly variable, characteristic impedance represents a somewhat artificial figure of merit, which is highly dependent on the specific definition used for the calculation. Thus, differing methods may result in a wide range of values for characteristic impedance. The compliance parameters determined from the pulse-contour method might therefore be a more reliable indicator of vascular elastic behavior.

The current study using pulse-contour analysis and others using Fourier analysis show decreased vascular compliance in CHF. Many mechanisms have been suggested for the stiffer, less distensible, vascular behavior, including sodium retention and water logging, sympathetic nervous system stimulation, age, and a shift in compliance curve operating point. Because there was no significant difference in either age or mean pressure between groups in the current study, age and operating point shift could not be directly responsible for the observed compliance differences. Plasma norepinephrine and plasma renin activity are significantly elevated in heart failure, and the increased plasma norepinephrine is correlated with the hemodynamic and vascular resistance changes associated with heart failure.[24] Vascular compliance may also be affected by such sympathetic stimulation, and this possibility is currently under investigation. Further study is also needed to determine if this sympathetic response is the cause or effect of the decreased vascular compliance, increased vascular resistance, and hemodynamic changes observed in CHF.

Thus, although a functional relation between vascular compliance and the pathophysiology of heart failure is not available, these results implicate vascular compliance, particularly compliance of the more distal vessels, as the vascular property most significantly changed in heart failure. Further data are needed to assess the relation between these vascular changes and the severity of CHF and its response to therapy.

Effects of Upright and Supine Position on Cardiac Rest and Exercise Response in Aortic Regurgitation

WEI FENG SHEN, MSc(Med), GARY S. ROUBIN, MB, PETER J. FLETCHER, MB, PhD, CHRISTOPHER Y-P. CHOONG, MB, BRIAN F. HUTTON, MSc, PHILLIP J. HARRIS, MB, DPhil, and DAVID T. KELLY, MB

The effects of upright and supine position on cardiac response to exercise were assessed by radionuclide ventriculography in 15 patients with moderate to severe aortic regurgitation (AR) and in 10 control subjects. In patients with AR, heart rate was higher during upright exercise, but systolic and diastolic blood pressure and left ventricular (LV) output were similar during both forms of exercise. LV stroke volume and end-diastolic volume were not altered during supine exercise. LV end-systolic volume increased and ejection fraction decreased during supine exercise, but both were unchanged during upright exercise. Of 15 patients, 5 in the upright and 12 in the supine position had an abnormal LV ejection fraction response to exercise ($p < 0.01$). Right ventricular ejection fraction increased and regurgitant index decreased with both forms of exercise and was not significantly different between the 2 positions. Thus, posture is important in determining LV response to exercise in patients with moderate to severe AR.

(Am J Cardiol 1985;55:428–431)

Radionuclide ventriculography during both supine and upright exercise has been used extensively for noninvasive assessment of cardiac function in patients with aortic regurgitation (AR).[1–4] Posture has important physiologic effects on the cardiovascular system at rest and during exercise.[5,6] Recent studies have revealed significant differences in the hemodynamic and cardiac functional response to exercise with different body positions in normal persons[7,8] and patients with coronary artery disease[8–10] or heart failure.[11] These effects of posture on exercise response may be especially relevant in patients with AR because of underlying alterations in loading conditions.[1–4] This study compares cardiac performance, at rest and during exercise, in both supine and upright positions, in patients with AR.

Methods

Patients: Fifteen patients (13 men, 2 women), aged 26 to 53 years (mean 42) with isolated, moderate to severe AR were studied (AR group). Eight patients had undergone cardiac catheterization, which documented isolated AR of angiographic grade 3/4, no mitral regurgitation and normal coronary arteries. The other 7 patients had clinical signs of isolated, moderately severe AR, with diastolic precordial basal murmur, pulse pressure greater than 55 mm Hg and cardiomegaly on radiograph. Echocardiography showed a left ventricular (LV) end-diastolic dimension greater than 6.0 cm, diastolic fluttering of the mitral valve and no coexistent valvular lesions. All patients who did not undergo catheterization were younger than 40 years and had no angina and segmental wall motion abnormalities on radionuclide angiography at rest and during exercise. All patients were in sinus rhythm.

Ten patients (9 men, 1 woman), aged 36 to 56 years (mean 45), with contrast angiographically normal LV function and coronary arteries were selected as a control group. All patients underwent catheterization because of atypical chest pain. The mean LV end-diastolic pressure did not differ before (6.8 ± 1.8 mm Hg) and after (8.0 ± 2.1 mm Hg) LV angiography. No patient had valvular disease and all had a normal electrocardiogram during exercise testing and were in sinus rhythm.

Study design: Studies were carried out at rest and during exercise in both supine and upright positions. The order of positions of exercise was randomly allocated; 6 patients exercised upright first and 9 patients supine first. A rest period of 20 minutes preceded each baseline measurement obtained and a 2-hour rest period separated the 2 exercise tests. Patients were positioned on an exercise table (Atomic Products) mounted with an electronically braked ergometer (Siemens Elema). Special care was taken to minimize the movement of

*$p < 0.05$, †$p < 0.01$ rest vs exercise in the supine or upright position; ‡$p < 0.05$, §$p < 0.01$ supine vs upright at rest or during exercise.

DBP = diastolic blood pressure; HR = heart rate; LVCO = left ventricular output; LVEDV = left ventricular end-diastolic volume; LVEF = left ventricular ejection fraction; LVESV = left ventricular end-systolic volume; LVSV = left ventricular stroke volume; RI = regurgitant index; RVEF = right ventricular ejection fraction.

the chest during exercise; the shoulders and the waist were fastened to the table with the restraining harness and seat belt. During supine exercise, the ergometer was positioned so that the axle was set at the table height. In the upright study, the patients sat at 80 to 90° to the horizontal with their feet 30 cm below the table height. In both positions, patients were instructed to hold but not grip the hand supports to avoid isometric contractions. Exercise in each position was continuous, multistage and symptom-limited. The initial workload of 15 W was increased by 15 W every 3 minutes. The pedal speed was held at a constant rate of 60 rpm. During exercise, the 12-lead electrocardiogram was recorded every minute and duplicate cuff measurements of blood pressure and radionuclide count data were obtained during the last 2 minutes of each exercise level. The phase IV Korotkov sound (muffling) was recorded as diastolic pressure.

Radionuclide determination of cardiac function: Red blood cells were labeled in vivo with 25 mCi of technetium-99m. Radionuclide data were collected with a single-crystal gamma camera (Technicare Ohio Sigma 420) as previously described.[12–14] LV end-diastolic volume and ejection fraction were estimated by a nongeometric technique validated in our laboratory.[12–14] LV end-systolic volume and stroke volume were calculated by end-diastolic volume and ejection fraction, and LV output was stroke volume times heart rate.

The right ventricular end-diastolic and end-systolic regions of interest were defined according to a standard method.[14] We previously showed that right ventricular ejection fraction measured by gated equilibrium method correlates well with that derived from the first-pass technique, and radionuclide regurgitant index (LV to right ventricular stroke count ratio) is closely related to angiographic regurgitant fraction.[14]

Statistical analysis: Results are given as mean ± standard deviation. Data at rest and during exercise at maximal workload in the 2 positions were analyzed by 2-way analysis of variance with Newman-Keuls multiple comparison test.[15] Difference between correlated proportions was compared by McNemar test.[16] A p value <0.05 was considered significant.

Results

Exercise tolerance and hemodynamics: The mean maximal workload achieved was similar during upright and supine exercise in the control (103 ± 26 vs 101 ± 23 W) and AR group (98 ± 40 vs 94 ± 38 W).

The hemodynamic and cardiac functional data are summarized in Table I. In each group, at rest and during exercise heart rate was higher in the upright position, and blood pressure and LV output were similar in both positions. Stroke volume was lower at upright rest in both groups, but was similar during both forms of exercise in the control group, and was higher during upright exercise in the AR group.

For both groups, heart rate, blood pressure and LV output increased from rest to exercise in the 2 positions. Stroke volume increased during both forms of exercise in the control group, but was unchanged during supine exercise in the AR group.

Cardiac function and regurgitant index: In each group, LV end-diastolic volume fell at upright rest, but was similar during both forms of exercise. LV end-systolic volume was smaller at upright rest in the control group, but was similar in both positions in the AR group. LV end-systolic volume was smaller during upright than during supine exercise in each group. At rest, LV ejection fraction was unaltered by the position in the control group, but decreased in the upright position in the AR group. LV ejection fraction was higher during upright than during supine exercise in both groups.

Exercise-induced changes in LV volumes and ejection fraction varied depending on both the position and the presence of AR. In control patients LV end-diastolic volume increased during both forms of exercise; in contrast, in patients with AR LV end-diastolic volume did not change during supine exercise. LV end-systolic volume decreased with exercise in the 2 positions for the control group, but it increased during supine exercise and was unchanged during upright exercise in the AR group. The mean LV ejection fraction increased during both forms of exercise in the control group, with all patients having an increase of at least 5% in the 2 positions. In contrast, LV ejection fraction decreased during supine exercise and was unchanged during upright exercise in the AR group. Of 15 patients, 12 in the supine position but only 5 in the upright position had an abnormal LV ejection fraction response to exercise (decreased or increased less than 5%) ($p < 0.01$) (Fig. 1).

In each group, there were no significant differences in right ventricular ejection fraction and regurgitant index between the 2 positions at rest and during exercise. During both forms of exercise, right ventricular ejection fraction increased in both groups; regurgitant index did not change in the control group and decreased in the AR group.

Discussion

This study of patients with moderate to severe AR shows that upright and supine body positions alter LV function at rest and during exercise. The supine position was frequently associated with an abnormal LV response to exercise in AR.

Effect of posture on hemodynamics and exercise tolerance: The higher upright heart rate at rest and during exercise in our control and AR patients may be a result of increased sympathetic and reduced vagal tone.[6] This agrees with previous findings in normal subjects[7,8] and in patients with heart disease.[9–11] In the upright position, LV stroke volume was lower at rest in both groups, presumably because of decreased LV preload (end-diastolic volume). During exercise, LV stroke volume was unchanged in the supine and slightly increased in the upright position for patients with AR, but neither differed significantly from the value at supine rest. These responses are different from those in the control group and may suggest a limited LV contractile reserve in these patients.[17] Because our patients had hemodynamically moderate to severe AR, these changes also may differ from those in patients with mild AR. Maximal attained external workload was comparable during both forms of exercise, probably because of a similar maximum forward cardiac output achieved,[18,19] since total LV output and regurgitant flow estimated by radionuclide regurgitant index[20] were similar during exercise in the 2 positions.

Effect of posture on left ventricular volumes and ejection fraction: The alterations in rest and exercise LV end-diastolic volume in the 2 positions may be explained by the effect of change in body position on systemic venous return,[21] as the degree of AR was not affected by position. During leg exercise, the blood volume pooled in the dependent regions is shifted into the intrathoracic space by the action of the muscle pump and sympathetic reflex venoconstriction.[6,19,22] Because systemic venous return is markedly enhanced by muscular exercise itself regardless of body position, LV end-diastolic volume would be expected to achieve similar levels during both supine and upright exercise. This agrees with previous findings in a preliminary study.[23]

A smaller LV end-systolic volume with similar systolic blood pressure at upright rest in control patients may represent an increased contractile state associated with the increased heart rate to compensate for the decreased end-diastolic volume.[7,8] In contrast, the LV end-systolic volume at rest was similar in both supine and upright positions in patients with AR. During both forms of exercise, the decrease in LV end-systolic volume seen in control patients probably resulted from the combination of effects of increased myocardial contractility and decreased afterload.[24] This was not observed in patients with AR, as LV end-systolic volume increased during supine exercise and was unchanged during upright exercise. The smaller LV end-systolic volume during upright exercise in both control and AR groups may result from a higher myocardial contractile state in the upright position[7,8] and an altered afterload.[24–26]

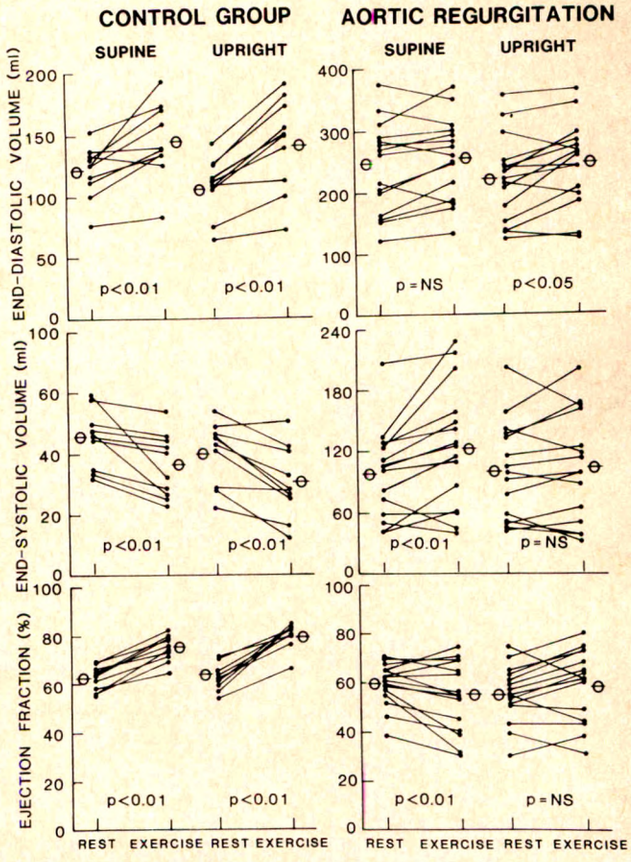

FIGURE 1. Effects of posture on left ventricular volume and ejection fraction response to exercise in the control group and patients with aortic regurgitation. Individual patients are represented by **closed circles** connected by **solid lines.** The **open circles** at the sides of each panel are the means. NS = not significant.

LV ejection fraction was similar at rest and increased significantly during both forms of exercise in control patients, consistent with previous findings in normal subjects.[7,8] In contrast, ejection fraction at rest was significantly lower in the upright position in patients with AR, and may be due to decreased preload without a compensatory increase in contractility. During exercise, mean LV ejection fraction decreased significantly in the supine position, with 12 of 15 patients failing to have an increase by at least 5%. This agrees with previous findings.[1,2] In contrast, mean LV ejection fraction was unchanged during upright exercise and was higher than that during supine exercise. An abnormal LV ejection fraction response to exercise was significantly less frequent in the upright position, suggesting that changes in loading conditions and contractility during exercise in the upright position may tend to mask LV dysfunction.[24–26]

Methodologic considerations: Separation of ventricular and atrial activities in the left anterior oblique projection may be more difficult in the supine than in the upright position. Since all our patients had no mitral regurgitation and atrial enlargement, the overlap between the ventricles and the atria may be small. A consistent approach was used for both positional studies in each patient, and LV and right ventricular regions of interest were defined on a stroke volume image. Thus, this source of error should be minor. In this study, as a fixed attenuation correction factor was applied for all patients; this may introduce some error in individual volume estimations.[27] However, our findings are based on changes in volume within individual patients, and the small error of volume estimation should not affect our conclusions.

In patients with moderate to severe AR, hemodynamics and cardiac function vary with posture at rest and particularly during exercise. Measurements in 1 position should not be compared with those obtained in another either at rest or during exercise in the individual patient. Because exercise-induced LV dysfunction occurs significantly more often during supine exercise, this position may be preferred for assessing LV functional capacity in asymptomatic patients with AR.

Electrocardiographic Observations in Clinically Isolated, Pure, Chronic, Severe Aortic Regurgitation: Analysis of 30 Necropsy Patients Aged 19 to 65 Years

WILLIAM C. ROBERTS, MD, and PAUL J. DAY*

Certain electrocardiographic findings are described in 30 necropsy patients with clinically isolated pure, chronic, severe aortic regurgitation. They were 19 to 65 years old (mean 45). The hearts of the 22 men ranged in weight from 430 to 1,110 g (mean 717) and of the 8 women, from 375 to 950 g (mean 638). Four had grossly visible left ventricular (LV) scars. All but 1 patient was in sinus rhythm. The PR interval was >0.20 second in 8 patients (28%) and the QRS duration was ≥0.12 second in 6 patients (20%). Only 5 patients (17%) had 1 or more ventricular premature complexes recorded on the resting electrocardiogram analyzed. The mean QRS amplitude for each of the 12 leads averaged 23 mm. The highest mean QRS voltage occurred in leads V_2 and V_3 (each 38 mm), and the lowest in lead aVR (11 mm). The mean QRS voltage in V_5 was higher than in V_6 (33 vs 28 mm) and in 22 patients (73%) the QRS voltage in V_5 was higher than in V_6. The sum of the S wave in V_1 plus the larger of the R wave in V_5 or V_6 (Sokolow-Lyon index) averaged 51 mm and in only 22 patients (73%) was it >35 mm. The Romhilt-Estes voltage criteria for LV hypertrophy was fulfilled even less frequently, despite the severe degrees of LV hypertrophy in the patients studied. The total 12-lead QRS amplitude in the 30 patients ranged from 109 to 428 mm (mean 272) (10 mm = 1 mV) and in 27 patients (90%) it was >175 mm. The ratio of total 12-lead QRS voltage to heart weight in the 30 patients with aortic regurgitation was 0.42, only slightly higher than that in previously studied adults with severe aortic stenosis (0.39), an observation indicating that cavity dilatation does not magnify the QRS voltage generated by a given mass of myocardium.

(Am J Cardiol 1985;55:431–438)

Although many studies are available on electrocardiographic findings in patients with aortic valve stenosis, few studies have described electrocardiographic findings in patients with chronic aortic regurgitation (AR). Electrocardiographic QRS voltage observations[1–7] in patients with chronic AR usually have been limited to analysis of the presence of left ventricular (LV) hypertrophy as determined by criteria proposed by Sokolow and Lyon[8] or Romhilt and Estes.[9] No studies of patients with fatal, pure, isolated AR have compared electrocardiographic findings during life to necropsy cardiac findings. Such a correlation is the purpose of this report. The amplitude of the QRS complexes in all 12 leads, in addition to that of certain R and S waves, was measured in all patients.

Definitions

The terms describing AR in the patients were defined as follows: *Clinically isolated*—valvular dysfunction limited to the aortic valve. Function of the mitral, tricuspid and pulmonic valves was normal. *Pure*—no peak systolic pressure gradient present between left ventricle and systemic artery. *Chronic*—evidence of severe AR for more than 6 months. *Severe*—AR graded 3+ or 4+/4+ by aortic root angiogram or symptoms of cardiac functional class III or IV (New York Heart Association criteria) and the symptoms attributable only to AR.

Patients

Inclusion criteria for this study were (1) presence of chronic, isolated, pure, severe AR; (2) age at death older than 15 years; (3) interval between aortic valve replacement and death within 2 months; (4) availability of 12-lead electrocardiogram (ECG) recorded either preoperatively or within 1 month of death; and (5) heart weight >350 g in women and >400 g in men. The ECG analyzed was always that obtained just before aortic valve replacement (19 patients) or in the patients who did not undergo aortic valve operation,[10] the one recorded in the last month of life. The amplitude of the QRS complexes was measured from the peak of the R wave to the maximal dip of the S or Q wave, whichever was greater (Fig. 1). The cardiac catheterization data were obtained just before aortic valve replacement (16 patients) or within 6 months of death in the patients who did not undergo aortic valve operation (6 patients).

Thirty patients fulfilled the inclusion criteria. Certain clinical and morphologic findings for these patients are summarized in Table I. In all 30 patients the clinical records were examined, the heart in each was examined initially and the hearts in 25 patients were reexamined. The amounts of coronary arterial narrowing present was determined by examination of 5-mm transverse sections of the 4 major coronary arteries by a method delineated elsewhere.[11] Of the 30 patients, the cause of the AR was infective endocarditis that had healed in 8,[10] cardiovascular syphilis in 6,[12] ankylosing spondylitis in 5,[13] Marfan's syndrome in 5,[14] uncertain cause

in 4, trauma in 1[15] and systemic hypertension in 1.[16] The patients were 19 to 65 years old (mean 45); 22 (73%) were men and 8 (27%) were women. Of the 30 patients, 29 had evidence of congestive heart failure (New York Heart Association functional class III or IV); patient 2 (Table I) was asymptomatic but had aortic valve replacement because of a LV end-systolic dimension >55 mm by echocardiogram. Of the 30 patients, 22 had left-sided cardiac catheterization and aortic root angiograms. LV peak systolic pressures ranged from 88 to 190 mm Hg (mean 133), LV end-diastolic pressures from 8 to 80 mm Hg (mean 32) and systemic arterial end-diastolic pressures from 20 to 65 mm Hg (mean 42). Nineteen patients died of complications of aortic valve replacement; the other 11 died from chronic congestive heart failure secondary to the AR.

At necropsy, the hearts in the 22 men weighed 430 to 1,100 g (mean 717) (normal ≤400 g) and the hearts in the 8 women weighed 375 to 950 g (mean 638) (normal ≤350 g). These weights were total heart weights, not just LV weights. A grossly visible, transmural (involving all the inner half and a portion or all of the outer half of the wall) LV scar (healed myocardial infarct) was present in 4 patients, but none during life had a clinical event diagnosed as, or compatible with, acute myocardial infarction.

The comparison of means was done using an unpaired Student *t* test, the comparison of ratios was done using a chi-square test, and the correlation coefficients were calculated using a Pearson's product moment test. Significance was judged if the test yielded a p valve <0.05.

Results

General electrocardiographic observations: Electrocardiographic findings are summarized in Tables I and II. The total 12-lead QRS amplitude in the 30 patients ranged from 109 to 428 mm (mean 272) (10 mm = 1 mV), and in 27 patients (90%) it was >175 mm (Table II). The relation of the total 12-lead QRS voltage to heart weight in the 30 patients is illustrated in Figure 2. The method of measuring various QRS complexes for this measurement is illustrated in Figure 1. The mean QRS voltage for each of the 12 leads in each patient was 23 mm. The individual and mean QRS amplitudes in each of the 12 leads is displayed in Table II. The highest mean QRS voltage occurred in leads V_2 and V_3 (each 38 mm), and the lowest mean voltage in lead aVR, 11 mm. The QRS mean voltage in V_5 was higher than that in V_6 (33 mm vs 28 mm); in 22 patients (73%), the QRS voltage in V_5 was higher than that in V_6.

Various previously recommended electrocardiographic QRS voltage criteria (summarized by Murphy et al[17]) for LV hypertrophy and the frequency of their occurrence in our 30 patients with chronic AR are summarized in Table III. A few criteria have been slightly modified to allow the number designating the upper limit of normal to end in a 0 or a 5, and to allow the elevated value to always be greater than a certain number rather than equal to or greater than a certain number. Of the 18 criteria analyzed, only 1 upper-limit number was evaluated in 3, two values were analyzed in 14, and 4 values in 1. Thus, a total of 35 values were analyzed for the 18 criteria: 34 were measurements in millimeters of QRS voltage and 1 was a ratio. The 2 criteria that had the highest positive frequency were the sum of the tallest limb-lead R wave plus the deepest limb-lead S wave >15 mm (90%, 27 of 30 patients) and the sum of the voltage of the QRS complex in all 12 leads, >175 mm (90%). The sum of the S wave in lead V_1 plus the larger of the R wave in V_5 or V_6 was >35 mm in 22 patients (73%). The sum of the larger S wave of leads V_1 or V_2 plus the larger of the R wave of V_5 or V_6 was >35 mm in 26 patients (87%) and >40 mm in 22 patients (73%). The sum of the deepest S wave in leads V_1, V_2 and V_3 plus the tallest R waves in leads V_4, V_5 and V_6 was >35 mm in 26 patients (87%), >40 mm in 25 patients (83%), >45 mm in 22 patients (73%) and >50 mm in 21 patients (70%). The tallest R wave plus the deepest S wave in any single V lead was >35 mm in 19 patients (63%).

The S-wave amplitude in lead V_1 ranged from 9 to 60 mm (mean 23); the R-wave amplitude in lead V_5 ranged from 9 to 64 mm (mean 25) and in V_6, from 11 to 47 mm (mean 25). The sum of the S wave in V_1 and the larger of the R waves in either V_5 or V_6 (Sokolow-Lyon index) ranged from 22 to 110 mm (mean 51). The deepest S wave in leads V_1, V_2 and V_3 ranged from 12 to 70 mm (mean 38) and in 23 patients (77%) it was >25 mm. The largest precordial S wave was in lead V_1 in 3 patients (10%), in lead V_2 in 12 patients (40%), in lead V_3 in 13 patients (43%) and in V_4 in 2 patients (7%). The average S-wave amplitude was higher in lead V_2 than V_1 (40 vs 24 mm).

The largest R wave in leads V_4, V_5 and V_6 ranged from 12 to 64 mm (mean 30) and in 19 patients (63%) it was >25 mm; the largest precordial R wave was in lead V_4 in 2 patients (7%), in V_5 in 19 (63%) and in V_6 in 9 (30%). The mean height of the R wave in both leads V_5 and V_6 averaged 25 mm. The R wave in V_6 was larger than the R wave in V_5 in 9 patients (30%).

Of the 30 patients, 29 (97%) were in sinus rhythm. The PR interval in them ranged from 0.16 to 0.36 second (mean 0.21) and it was >0.20 second in 8 (28%) patients. The width of the QRS complex ranged from 0.06 to 0.14 second (mean 0.10); in 6 (20%) patients it was ≥0.12 second. The QRS axes are listed in Table II. Of the 30

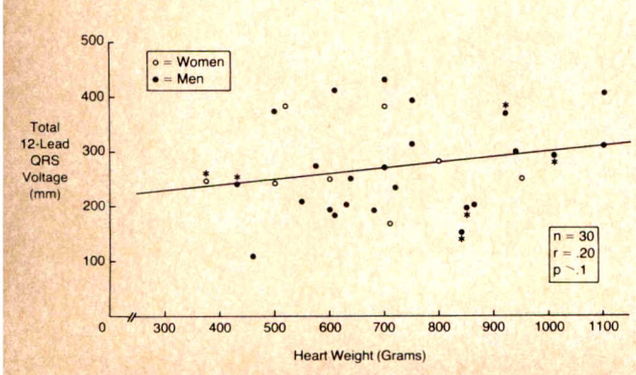

FIGURE 2. Relation of the total 12-lead QRS voltage (mm) to heart weight (grams) in the 30 patients with severe, pure aortic regurgitation. **Asterisks** designate the patients in whom the widths of the QRS complexes were at least 0.12 second.

Comparison of patients younger than 40 years and older than 40 years: No significant differences were observed between the 13 younger and the 17 older (older than 40 years) patients in sex ratio; percent with angina pectoris, widened QRS complexes or LV scarring; mean heart weight (677 vs 710 g); average Sokolow-Lyon index (50 vs 50 mm), or mean LV peak-systolic pressure (137 vs 129 mm Hg). The percent with significant (>75% cross-sectional area) coronary arterial narrowing was different (0 of 13 vs 5 of 17) ($p < 0.05$).

Comparison of patients with and without angina pectoris: No significant differences were observed between the 6 patients with and the 24 patients without angina in mean age; sex ratio; frequency of coronary arterial narrowing or LV scarring; average total 12-lead QRS voltage (287 vs 267 mm); mean Sokolow-Lyon index (55 vs 49 mm); or LV peak systolic pressure (117 vs 138 mm Hg). The frequency of widened QRS complexes was different (3 of 6 vs 3 of 24) ($p < 0.05$).

Comparison of patients with total 12-lead QRS voltage 250 mm or less to those with total voltage more than 250 mm: No significant differences were observed between the 17 patients with total 12-lead QRS voltage ≤250 mm and the 13 patients with larger total voltage in mean age, sex ratio, percent with significant coronary arterial narrowing, LV scarring, angina pectoris or widened QRS complexes; mean LV peak systolic pressure (135 vs 133 mm Hg), or mean heart weight (648 vs 760 g). The average Sokolow-Lyon index was different (39 vs 65 mm) ($p < 0.001$).

Comparison of patients with normal and abnormal Sokolow-Lyon indexes: No significant differences were observed between the 8 patients with normal and the 22 patients with abnormal (>35 mm) indexes in mean age; sex ratio; percent with narrowed coronary arteries, LV scar, angina pectoris or widened QRS complexes, or mean LV peak systolic pressure (131 vs 136 mm Hg). The average total 12-lead QRS voltage was different (210 vs 296 mm) ($p < 0.05$). The Sokolow-Lyon index in the 22 patients in whom this index was >35 mm ranged from 38 to 110 mm (mean 61) and their hearts weighed 430 to 1,100 g (mean 729); in the 8 patients in whom the Sokolow-Lyon index was <35 mm, the index ranged from 22 to 34 mm (mean 27) and their hearts weighed 375 to 865 g (mean 606).

Comparison of patients with normal and widened (more than 0.12 second) QRS complexes: No significant differences were observed between the 24 patients with QRS widths <0.12 second compared to the 6 with longer widths in mean age; sex ratio; percent with narrowed coronary arteries, LV scar or angina pectoris; mean heart weight (686 vs 738 g); average total 12-lead QRS voltage (276 vs 249 mm); mean Sokolow-Lyon index (51 vs 44 mm), or mean LV peak systolic pressure (138 vs 117 mm Hg). The frequency of angina pectoris was different ($p < 0.05$): angina was present in 3 of 24 patients with normal-width QRS complexes and in 3 of 6 patients with widened complexes ($p < 0.05$).

Comparison of patients with left ventricular peak systolic pressure less than 140 mm Hg to those with pressures greater than 140 mm Hg: No significant differences were observed between the 14 patients with the lower compared to the 8 patients with the

higher (>140 mm) pressures in age; sex ratio; percent with angina, coronary arterial narrowing, LV scar, or widened QRS complexes; mean heart weight (696 vs 746 g), average total 12-lead QRS voltage (271 vs 267 mm), or mean Sokolow-Lyon index (52 vs 44 mm).

Comparison of patients with hearts weighing 600 g or less to those with hearts weighing more than 600 g: No significant differences were observed between the 10 patients with hearts ≤600 g compared to the 20 patients with larger hearts in mean age; sex ratio; percent with angina pectoris, coronary arterial narrowing, LV scar or widened QRS complexes; average total 12-lead QRS voltage (252 vs 280 mm); mean Sokolow-Lyon index (45 vs 53 mm), or mean LV peak-systolic pressure (130 vs 135 mm Hg).

Comparison of patients with and without coronary arterial narrowing: The mean age was older among the 5 patients with narrowing >75% in cross-sectional area of 1 or more major coronary arteries compared to that among the 25 patients without (57 vs 42 years), and the percent with LV scarring was higher (2 of 5 vs 2 of 25) ($p < 0.05$). No significant differences were observed between the 2 groups in sex ratio; percent with angina or widened QRS complexes; mean heart weights (729 vs 688 g); average total 12-lead QRS voltage (243 vs 277 mm); mean Sokolow-Lyon index (47 vs 51 mm), or mean LV peak-systolic pressure (138 vs 140 mm Hg).

Comparison of patients with and without left ventricular scarring: Except for a higher frequency of coronary arterial narrowing in the patients with LV scars (2 of 4 vs 2 of 26) ($p < 0.05$), no significant differences between these groups occurred in age; sex ratio; percent with angina or widened QRS complexes; mean heart weight (661 vs 701 g); average total 12-lead QRS voltage (249 vs 274 mm); mean Sokolow-Lyon index (50 vs 50 mm) or mean LV peak-systolic pressure (132 vs 135 mm Hg).

Discussion

Patients with chronic severe AR generally have hearts of greater weight than that observed in other conditions.[18] Thus, these patients should have larger QRS voltages than observed in other conditions. In addition to measuring R and S waves in 1 or more leads for LV hypertrophy as suggested by many investigators and summarized by Murphy et al[17] and in Table III, we measured the total QRS voltage in all 12 leads in each patient and compared its usefulness to that of other voltage criteria for LV hypertrophy.

Because patients with chronic, severe AR generally have the largest human hearts, these persons would appear to be the ideal group to examine the usefulness of the various QRS voltage criteria for LV hypertrophy. Many studies, of course, have compared LV mass determined at necropsy[9,19] or by angiography[20] or echocardiography[21–23] to QRS voltage, but few of the previous studies have included patients with chronic, severe, pure AR. All previous studies have demonstrated that all QRS voltage criteria for LV hypertrophy are unreliable. The present study demonstrates the same finding, but in a group of patients with larger hearts than those studied previously. Our patients as a group had hearts that weighed roughly 2 times normal.

The Sokolow-Lyon index[8] (sum of the S wave in V_1 plus the larger of the R wave in either V_5 or V_6), the most widely used QRS voltage criterion for LV hypertrophy, was >35 mm, i.e., abnormal, in only 22 of our 30 patients (73%) whose mean heart weight was 696 g. The QRS voltage for LV hypertrophy advocated by Romhilt and Estes[9] fared even worse, although these 2 investigators also incorporated non-QRS-voltage criteria for LV hypertrophy. Only 8 of our 30 patients (27%) had an R wave in the 6 limb leads ≥20 mm and only 5 (17%) had an S wave in these leads ≥20 mm (In our Table III, we use the criteria >20 mm rather than ≥20 mm to aid in comparisons to other criteria.); 23 patients (77%) had an S wave in leads V_1, V_2 and V_3 ≥25 mm and 20 (67%) had an R wave in leads V_4, V_5 and V_6 ≥25 mm. (Again, in the table we modified these voltage criteria to >25 mm rather than ≥25 mm.) A total of 25 patients (83%), however, satisfied the Romhilt-Estes QRS voltage criteria in 1 or more of the 4 lead sites (R in limb leads ≥20; S in limb leads ≥20; S in V_1, V_2 and V_3 ≥25 and R in V_4, V_5 and V_6 ≥25 mm).

A better criterion of LV hypertrophy was the sum of the tallest R wave and deepest S wave in the 6 limb leads. This sum was >15 mm in 27 (90%) of 30 patients.

In contrast to the disappointing frequency of fulfillment of the Sokolow-Lyon, Romhilt-Estes and most other criteria (Table III) for LV hypertrophy in our 30 patients with chronic, severe AR, measurement of the sum of the height and depth of the QRS complexes in all 12 leads did appear useful. Although the upper limit of normal QRS voltage in each of the 12 electrocardiographic leads in adults without evidence of cardiac disease has been well established,[17,24–27] the upper limit of total 12-lead QRS voltage has not been established in human adults whose LV mass has been determined by necropsy or by an angiographic or echocardiographic means. It is likely, however, that the total 12-lead QRS voltage in adults over 30 or so years of age with normal sized hearts is <175 mm. Indeed, Richard B. Devereux (AJC Editorial Board Member), in his review of the present manuscript, stated that 12-lead QRS voltage was <175 mm in 87 of 92 clinically normal patients (95%) studied by him, P.N. Casale and P. Kligfield (unpublished observations), indicating that this criterion has good specificity (100 times number of normal subjects with negative test divided by total number of normal subjects tested). Using 175 mm as the upper limit of normal, 27 of our 30 patients (90%) had LV hypertrophy by this criterion.

In the present study we also examined 10 other variables, further analyzing each to compare patients with to those without 1 or more variables or to compare patients with greater than to those with less than a certain figure. A total of 90 comparisons were examined among the 10 variables. Of the 90, only 8 (9%) showed a significant ($p < 0.05$) difference in the variable analyzed. The 4 patients with transmural LV scars had a higher frequency of coronary narrowing (2 of 4 patients) than the 26 patients without LV scars (2 of 26 patients) ($p < 0.05$) and vice versa. Patients older than 40 years had a significantly higher frequency of coronary narrowing than did the younger patients ($p < 0.05$) and vice versa. Angina was significantly more frequent in pa-

TABLE IV Comparison of Total 12-Lead QRS Amplitude in Necropsy Patients with Chronic Aortic Regurgitation to Necropsy Patients with Aortic Valve Stenosis and Cardiac Amyloidosis

	Aortic Stenosis	p Value	Aortic Regurgitation	p Value	Cardiac Amyloidosis
No. of patients	50		30		30
Age (yr), range (mean)	16–65 (48)	NS	19–65 (45)	<0.001	21–93 (58)
Men (n)	36 (72%)	NS	22 (73%)	NS	15 (50%)
Women (n)	14 (28%)	NS	8 (27%)	NS	15 (50%)
Substernal pain (n)	34 (68%)	<0.01	11 (37%)	<0.05	4 (13%)
SA peak systole (mm Hg), range (average)	63–180 (112)	<0.001	96–200 (139)	<0.001	90–110 (104)
SA end-diastole (mm Hg), range (average)	34–88 (62)	<0.001	20–65 (42)	<0.001	60–80 (67)
Heart weight (g), range (mean)	380–880 (606)	<0.05	375–1110 (696)	<0.001	370–900 (532)
Narrowed coronary artery (n)	16 (32%)	NS	5 (17%)	NS	5 (17%)
Left ventricular scar (n)	7 (14%)	NS	4 (13%)	NS	4 (13%)
Total 12-lead QRS voltage (mm), range (average)	144–417 (257)	NS	109–428 (270)	<0.0001	58–199 (104)
Total 12-lead QRS voltage >175 mm, (n)	47 (94%)	NS	27 (90%)	<0.0001	2 (7%)

tients with QRS widths ≥0.12 second than in those with shorter QRS widths (3 of 6 vs 3 of 24) ($p < 0.05$) and, conversely, the patients with the normal Sokolow-Lyon indices had significantly lower average total 12-lead QRS voltage than did the 21 patients with an abnormal (>35 mm) Sokolow-Lyon index (210 vs 296 mm); conversely, the 17 patients with total 12-lead QRS voltages ≤250 mm had lower mean Sokolow-Lyon indexes than did the 13 patients with total 12-lead QRS voltages >250 mm (39 vs 65 mm) ($p < 0.001$).

Two other studies from this laboratory have used total 12-lead QRS voltage. One examined electrocardiograms in 50 necropsy patients with severe (LV systemic arterial peak systolic pressure gradients >50 mm Hg) aortic valve stenosis[28] and the other examined electrocardiograms in 30 necropsy patients with cardiac amyloidosis[29] (Table IV). Findings in these 2 groups of patients are summarized in Table IV and the findings are compared with those in the 30 patients with pure, chronic AR. The mean total QRS voltage was highest among patients with AR and lowest for those with amyloid. The percent of patients with AR or aortic stenosis having total 12-lead QRS voltage >175 mm was similar (90% and 94%), and 13 times higher than that in the amyloid group. The ratio of 12-lead QRS voltage to heart weight was slightly lower in the patients with aortic stenosis compared to those with pure AR (0.39 vs 0.42), indicating that cavity dilatation does not magnify the QRS voltage generated by a given mass of myocardium.

Myxoid Degeneration of the Aortic Valve and Isolated Severe Aortic Regurgitation

WARREN M. ALLEN, MD, JACK M. MATLOFF, MD, and MICHAEL C. FISHBEIN, MD

Clinical and pathologic data were reviewed in 55 patients who had valve replacement for pure aortic regurgitation (AR) during a 6-year period. The clinical histories established the cause for AR in 34 cases: 11 rheumatic, 13 infective endocarditis, 4 congenital, 4 associated with aortic aneurysms and 2 the Marfan syndrome. In the valves from the other 21 patients, 13 had myxoid degeneration, defined as significant disruption of the valve fibrosa and its replacement by acid mucopolysaccharides and cystic change. Myxoid degeneration was also the primary pathologic abnormality in the 2 patients with the Marfan's syndrome, in 3 patients with a history of rheumatic disease and in 1 patient with a history of infective endocarditis. The patients with myxoid degeneration of uncertain origin were predominantly elderly (average age 63 years), had a long-standing history of systemic hypertension (77%) and had coronary artery disease (46%); 85% were male. In these patients the replacement valves were not larger than those of the other groups studied, indicating that dilatation of the aortic anulus was not a significant factor in the pathogenesis of the valve disease. These findings indicate that myxoid degeneration of the aortic valve is common (36% of all valves examined) and, in many cases, may be secondary to long-standing systemic hypertension.
(Am J Cardiol 1985;55:439–444)

The spectrum of disease found in the aortic valve and aorta is varied and complex. Pathologists studying valves removed at surgery are faced with the often difficult problem of determining a cause for valve failure, based on the end-stage pathologic findings at the time of operation. In addition to rheumatic and syphilitic disease, congenital malformation, infective endocarditis, trauma, and several metabolic, connective tissue and inflammatory diseases have been recognized as causing severe aortic regurgitation (AR).[1–5] However, little information is available concerning the relative frequency of these disorders in patients who undergo isolated aortic valve replacement for severe AR. In this study, we reviewed the clinicopathologic features of 55 patients who required aortic valve replacement for pure AR at our institution from 1976 to 1982.

Methods

Pathologic study: Gross and histologic findings were reviewed in 55 aortic valves removed during surgery for pure AR, both with and without coronary artery bypass grafting. Gross findings of interest were the number and thickness of valve cusps; presence of fusion of commissures; presence and degree (graded mild, moderate or severe) of calcification; and the presence of perforations, tears, fenestrations or vegetations.

Histologic sections of formalin-fixed material processed routinely or with decalcification were reviewed retrospectively. Sections were stained with hematoxylin-eosin and alcian blue/PAS. Based on a consensus of 2 investigators, histologic findings were graded 0 to +3, indicating no, mild, moderate or severe abnormalities. The abnormalities so graded included valvular calcification, deposition of mature collagen, presence of increased amounts of acid mucopolysaccharides (AMP), disruption of the valve fibrosa and cystic degeneration of the spongiosa layer. The histologic material was also assessed for the presence or absence of inflammatory or thrombotic vegetations. The diagnosis of myxoid degeneration was strictly limited to valves that had +2 or greater AMP deposition and a +2 or greater disruption of the valve fibrosa in the absence of calcification or more than +1 fibrosis. Because the base of the valve leaflet and the nodule of Arantius normally contain increased AMP and fibrous tissue, these areas were excluded from evaluation.

Clinical data: We searched the patients' charts for the following clinical information: age; sex; cardiac risk factors (including admission blood pressure, history and degree of hypertension, documented coronary artery disease, elevated serum lipids and smoking); history of rheumatic heart disease; and history of infective endocarditis, syphilis, congenital heart disease, Marfan's syndrome and other cardiovascular diseases. Catheterization data, operative findings and the replacement valve type and size were also reviewed.

TABLE I Cause of Aortic Regurgitation

Cause		n
Rheumatic heart disease		11
Endocarditis		13
Acute	5	
Old	8	
Congenital		4
Bicuspid valve	2	
Subaortic stenosis	1	
Tetralogy of Fallot	1	
Aortic aneurysm		4
Marfan's syndrome		2
Unknown		21
Myxoid degeneration	13	
		55

Using both the clinical and pathologic data, the patients were grouped according to the origin of their valvular insufficiency. The 6 groups were as follows: rheumatic heart disease, endocarditis (acute and old), congenital, associated with aortic aneurysm, Marfan's syndrome, and unknown (Table I). No patient had aortic stenosis or any functional abnormality of other cardiac valves.

Controls: To determine whether any observed pathologic changes were indeed associated with the valvular dysfunction, a control group of valves was also studied. This group consisted of 17 aortic valves: 12 from the county medical examiner's office and 5 from our necropsy service. These valves were from patients who died of noncardiac causes with no history of valvular disease.

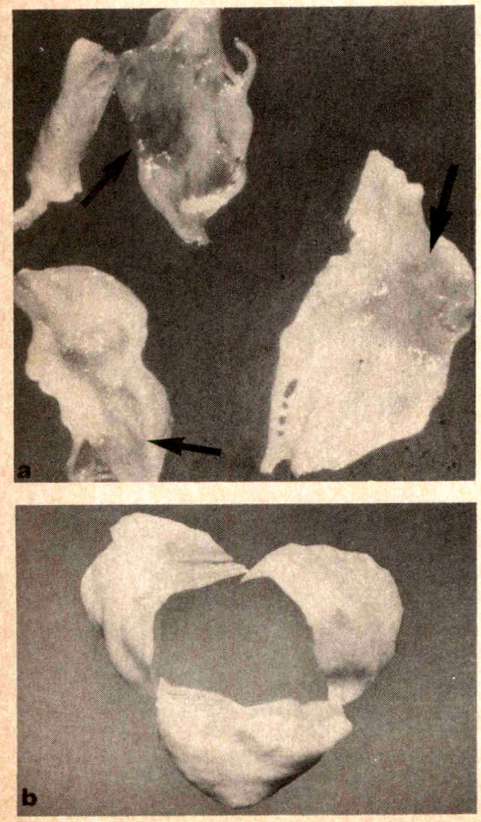

FIGURE 1. a, Myxoid degeneration of aortic valve. Thin, translucent regions are present in each leaflet (**arrows**). **b,** control aortic valve, which does not show this change.

Results

Clinical histories established the presence of rheumatic heart disease in 11 patients. In these predominantly male patients (Table II), aged 18 to 69 years, the period from onset of rheumatic disease was 15 to 50 years. Four patients had had additional episodes of infective endocarditis. In 4 patients the duration of heart failure was relatively long (3 to 7 years) and in the others it was recent (6 months or less) or not present. Two patients had coronary artery disease requiring simultaneous coronary bypass graft surgery. Two of 11 patients had a history of hypertension. Five of the excised valves showed fibrosis plus calcification, 3 showed nonspecific increased AMP and 3 of the valves had the histologic picture of myxoid degeneration. The replacement valves were, in general, large, with 9 of 11 measuring 27 mm or greater in diameter.

Thirteen patients had a history of endocarditis not associated with rheumatic heart disease. Five of these patients had acute endocarditis and presented with sudden-onset of AR. One patient had a ruptured cusp and 3 patients showed vegetations plus severe inflammation. The valve was severely calcified in one patient and had increased AMP in one; in the other 3 patients no underlying valvular pathology was found. Eight patients had a history of old bacterial endocarditis, ranging from 1 to 31 years in duration. None of these patients had a history of hypertension. Two of these patients had had congestive failure for as long as 3 years. The rest had a 6-month-or-less period of failure before valve replacement. The excised valves were fibrotic and often heavily calcified; fenestrations were prominent in 5. One valve showed only myxoid degeneration without fibrosis or calcification. The average replacement valve size was 26 mm.

Two patients with the Marfan's syndrome, a father and son, required valve replacement for AR. One had the simultaneous repair of an aortic aneurysm. Both of these valves showed pure myxoid degeneration and both required a 27-mm replacement valve.

Congenitally bicuspid valves accounted for AR in 2 patients. One valve was predominantly fibrotic with calcification and the other showed mild myxoid de-

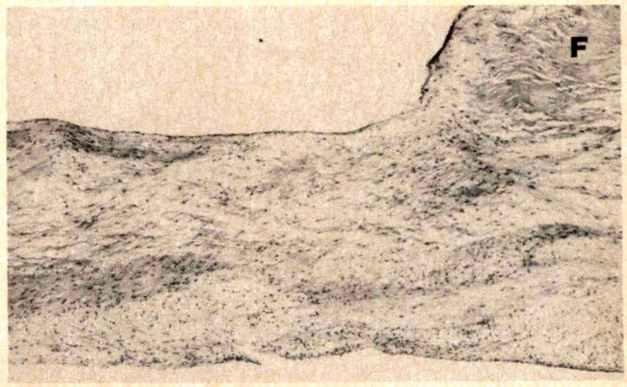

FIGURE 2. Key features of myxoid degeneration: disruption of the fibrosa (F) and increased acid mucopolysaccharides in the spongiosa. Alcian blue/PAS stain; original magnification × 16, reduced 51%.

* Pulmonary capillary wedge pressure.
AR = aortic regurgitation (by cine); CAD = coronary artery disease; C-E = Carpentier-Edwards valve; CHF = congestive heart failure; H = Hancock porcine valve; LVEDP = left ventricular end-diastolic pressure; SAP = systemic arterial pressure; SH = history of systemic hypertension; S-J = St. Jude's valve.

generation. Two other valves were insufficient secondary to congenital anomalies and were removed after repair of other lesions: 1 from a patient with tetralogy of Fallot and 1 from a patient with subaortic stenosis. At operation both valves were redundant and thin, and prolapsed, with in the latter case, large fenestrations. Histologic sections of the valves showed focal fibrosis and mildly increased AMP.

An aortic aneurysm severe enough to require simultaneous patch grafting was found in 4 patients, in addition to one of the patients with Marfan's syndrome. All 4 patients had coronary artery disease and 1 patient had a long history of hypertension. The excised valves from 2 of these patients had enlarged cusps showing focal to severe calcification, and the valves from all 4 patients showed fibrosis and increased AMP. The replacement valves were large, averaging 28 mm.

The largest category of patients was the unknown group, in which no definite cause for AR could be found. This group was separated into 2 subgroups on the basis of valve pathology: 13 of the 21 valves showed the pathologic findings of pure myxoid degeneration (Fig. 1 and 2). Table III defines the clinical features of this subgroup. With one exception, the patients were age 50 years or older (mean 63 ± 13 [± standard deviation]), and 11 of the 13 were males. None had features or findings of Marfan's syndrome. Three patients, the 2 women and a 26-year-old man, had a history of cardiac murmur for 7 years or longer. Ten patients had long-standing systemic hypertension, described as severe in 4. Because one of our criteria for hypertension was current treatment with antihypertensive medication, many of the patients with a history of hypertension may have had normal systolic blood pressures on admission. Furthermore, because of the development of functional AR, a widened pulse pressure with a low diastolic pressure was often encountered. Patients with a history of unresponsive hypertension, those requiring multiple antihypertensive drugs or those with a history of hypertensive complications were classifed as severely hypertensive. The valves removed were usually thinned with extensive cystic change and myxoid degeneration. Increased AMP was found in both the spongiosa and fibrosa of the valves. As stated earlier, 2+ destruction of fibrosa was found in all of these valves. Many of the valves also had nodular thickening with large "pools" of myxoid material intermixed with fibrosis. Replacement valves averaged 26 mm in diameter.

TABLE IV Clinical Characteristics of Patients in Whom the Cause of Valvular Insufficiency Was Unknown (Without Myxoid Degeneration)

Pt	Age (yr) & Sex	SAP (mm Hg)	SH	LVEDP (mm Hg)	CHF	AR (0–4+)	Replacement Valve	CAD	Increased AMP in Aortic Valve (0–3+)

* Pulmonary capillary wedge pressure.
AR = aortic regurgitation (by cine); CAD= coronary artery disease; C-E = Carpentier-Edwards valve; CHF = congestive heart failure; H = Hancock porcine valve; LVEDP = left ventricular end-diastolic pressure; SAP = systemic arterial pressure; SH = history of systemic hypertension.

The other 8 patients in the unknown group are summarized in Table IV. Their clinical features are not distinctive, but include long-standing hypertension in 4 and severe coronary artery disease in 4. Two patients had presented recently with heart failure; the rest had received medication for 2 to 40 years. The excised valves showed a somewhat variable pattern with a combination of fibrosis, focal calcification and increased AMP. Replacement valves averaged 26 mm in diameter.

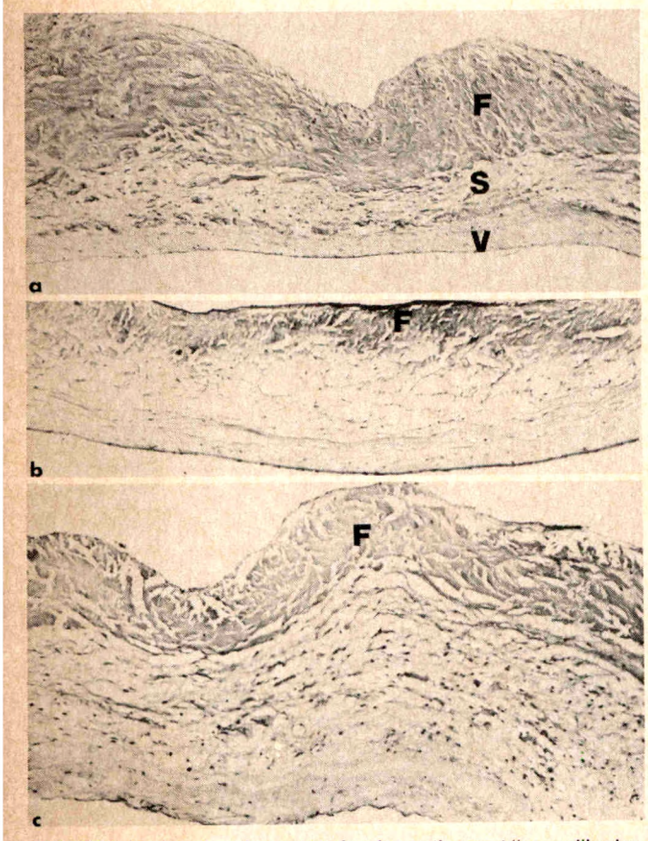

FIGURE 3. Aortic valves from control series. **a,** the most "normal" valve with distinct fibrosa (F), spongiosa (S) and ventricularis (V) layers. **b,** cystic change in the spongiosa. **c,** increased acid mucopolysaccharides in the spongiosa. In all of these examples (and all valves of the control series), the fibrosa is intact. Alcian blue/PAS stain; original magnification × 16, reduced 49.5%.

Follow-up of all patients at 2 months showed no complications. For 5 of the 13 patients follow-up at 1 year or longer was available. Of these patients, 2 were normal; 1 required a pacemaker for ventricular arrhythmias at 2 years; 1 patient had a mild perivalvular leak; and 1 died of a type I dissecting aortic aneurysm at 3 years. The last patient's prosthetic valve was described at operation as still functional.

Valves in the control group (n = 17 valves) were from patients 31 to 81 years old (mean 61); 10 were from men. Grossly, all valves were free of calcification, commissural fusion or vegetations (Fig 1). Focal areas of fibrous thickening were apparent as well as areas of relative translucency. Microscopic sections showed foci of 1+ cystic change limited to the spongiosa layer in 8 of the valves. Mildly (1+) increased AMP was present within the spongiosa in 7 valves. Most important, no valves had disruption of the fibrosa layer by AMP (Fig 3).

Discussion

Myxoid degeneration of the aortic valve was first described in a patient by Weaver et al, in 1957.[6] Read et al,[7] describing 3 such patients in 1965, considered it and the similar findings in the mitral valve as a possible forme fruste of Marfan's syndrome. Since then, several isolated cases of AR associated with myxoid degeneration of the valve leaflets have been reported.[8–14] In the past it was considered a rare finding, and there are few data regarding its frequency as a cause of AR. In contrast, myxoid degeneration of the mitral valve with prolapse is recognized as a common clinicopathologic entity. The reported frequency of mitral valve prolapse ranges from 6 to 17% of healthy adults.[8,15–17]

In this study of a large series of patients, myxoid degeneration was the primary pathologic abnormality in 36% (19 of 55) of all valves replaced for isolated, pure AR. In 2 patients the underlying disease was the Marfan's syndrome; in 3 there was a history of rheumatic heart disease, and 1 patient had a history of old bacterial endocarditis. In the remaining 13 patients a careful review of the clinical histories revealed no other commonly recognized primary cause for valvular insufficiency.

As demonstrated in our control group, it is well known that small amounts of increased AMP can be found in many valves. Using the strict criteria outlined in this

report and by others, pure myxoid degeneration requires a significant disruption of the valve fibrosa and its replacement by acid mucopolysaccharides, in the absence of fibrosis and calcification. Thus, it is actually the fibrosa that demonstrates degeneration. Whether the increased AMP is a primary or secondary phenomenon is uncertain. Presumably as a result of the degeneration of the fibrosa, the valve integrity is lost as the leaflets are progressively stretched and thinned, and the valve becomes incompetent. A defect in collagen biosynthesis has been suggested as an explanation for the floppy mitral valve syndrome by the finding of a marked increase in cross-linked procollagen and single chain procollagen.[18] Similarly, electron microscopy studies of floppy valves have shown granular cells containing collagen.[19,20] These cells are similar to those found in valves from patients with Hurler's syndrome, and may be related to an abnormal interaction between newly secreted collagen and acid mucopolysaccharides.

As with the mitral valve, the pathogenesis of myxoid degeneration of the aortic valve is uncertain. We studied the clinical features most likely to be associated with valve degeneration (Table V). Patients in the myxoid degeneration group have a fairly uniform clinical profile—85% were male, all except 2 were in their seventh decade or older, and they had a high incidence (46%) of coronary artery disease—but none of these features distinguishes it significantly from other groups. Although clinically the patients were free of features of Marfan's syndrome, we compared the replacement valve diameter among the different groups to see if valve stretching may have been related to a dilated aortic anulus, as in Marfan's syndrome. Valve diameters in the myxoid degeneration group were not larger than those of the other groups with AR. Although an enlarged anulus surely may contribute to valve stretching and thinning, it does not appear to explain AR in the cases of myxoid degeneration we observed.

Hypertension does appear to be associated with valve degeneration, and may be causally related. Long-standing hypertension was found in 10 of 13 patients (77%) in the myxoid degeneration group compared with 18% in all of the other groups combined. Although our groups are small, this difference was statistically significant (by chi-square analysis, $p = 0.003$).

The association of hypertension and AR that we have documented pathologically has been suspected clinically since 1920, when Osler noted the presence of diastolic murmurs in arterial hypertension.[21] Phonocardiographic evidence was obtained in 1960 by Puchner et al,[22] who documented diastolic murmurs in 15 patients with hypertension. They believed that this indirect evidence of AR was related to hypertension, but the clinical features of their patients were not fully described and there was no pathologic follow-up on the valves. Waller et al[23] recently described 4 patients with hypertension in whom severe AR developed, requiring valve replacement. A detailed histologic analysis of the valves was not included in their study, but there was no mention of valve thickening or calcification. The means by which hypertension effects such a change can only be surmised, but may be related to accelerated disruption of collagen in elderly patients who may have limited capacity for collagen synthesis, thus causing attrition and progressive degeneration of the valve fibrosa.

TABLE V Clinical Features of Patients with Aortic Regurgitation

Cause	Mean Age (yr)	CAD	Mean Prosthetic Valve Diameter (mm)	SH
Unknown				
Myxoid degeneration	63	6/13	26	10/13*
Other	65	3/8	25	4/8
Rheumatic	49	2/11	27	2/11
Endocarditis				
Acute	43	0/5		0/5
Old	51	3/8	26	0/8
Aortic aneurysm	67	4/4	28	1/4
Marfan's syndrome	37	0/2	27	0/2

* $p = 0.003$
CAD = coronary artery disease; SH = systemic hypertension.

The severity of the degeneration in our 13 patients indicates a pathologic process that may carry over into the postoperative period. A perivalvular leak developed in 1 patient and fatal dissecting aortic aneurysm in another. This is in keeping with reports of increased postoperative problems in myxoid degeneration of the mitral valve,[8] although the pathogenetic mechanisms may be different.

One other feature of note is that 3 of our patients with myxoid degeneration, the 2 female patients and a young male patient all had long-standing asymptomatic cardiac murmurs. Perhaps these patients, who do not fit well into the elderly male hypertensive category, represent a group with an inherent congenital defect but without other traits of Marfan's syndrome. These patients may or may not remain asymptomatic until the elderly period. Their high systolic pressures may be simply a reflection of their AR rather than a generalized hypertensive process. However, their inclusion in the total group emphasizes our overall finding that myxoid degeneration of the aortic valve is not rare, and may in fact be one of the most common pathologic entities associated with severe AR.

Acknowledgment: We acknowledge the generous assistance of Dr. Ronald Kornblum and the Los Angeles County Medical Examiners Office for allowing us to review their material.

Introducing the non-invasive catheter.

Unprecedented analysis of cardiac activity from outside the body.

NCCOM3™ is a revolutionary, real-time, beat-to-beat cardiac monitoring system that gives you precise, continuous measurements of your patients' complete hemodynamic status—with just the touch of a button.

NCCOM3 does everything you'd expect from catheterization, plus much more, without the trauma of invasion. APPLICATION OF EIGHT ECG SKIN ELECTRODES IS ALL THAT'S REQUIRED.

Continuous measurement of six hemodynamic variables.

- Stroke Volume
- Cardiac Output
- Heart Rate
- Ventricular Ejection Time
- Index of Thoracic Fluid Level
- Index of Blood Ejection Velocity (Contractility)

A new dimension in clinical management versatility.

- Monitoring cardiac activity post-anesthesia
- Evaluating cardiac rehabilitation therapy
- Quantify effects of periodic A-V asynchrony
- Intraoperative patient monitoring
- Quantification of vasoactive drug effects
- Continuous assessment of the ICU patient
- Stress testing
- Neonatal and pediatric cardiovascular and hydration assessment
- Titration of intravenous diuretics
- Hemodynamic monitoring during labor
- Monitoring for the onset of pulmonary edema during administration of tocolytics.

NCCOM3 is the monitoring system for the 1980's.

NCCOM3 is a precise, convenient, versatile and inexpensive monitor designed to give maximum clinical information at minimum cost. For more information on how NCCOM3 can benefit you and your patients, simply return the coupon below, contact your BoMed representative or call us.

Visken® (pindolol)

5-mg and 10-mg Tablets

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE
Visken® (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS
Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS
Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/ kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

	Total (Volunteered and Elicited)		
Body System/ Adverse Reaction	Visken (pindolol) (N = 322) %	Active controls* (N = 188) %	Placebo (N = 78) %
Central Nervous System			
Anxiety	4	<1	1
Bizarre or Many Dreams	8	3	8

Skin			
Pruritus	2	<1	0
Rash	2	3	3

* Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

More than 7 million patient-years of experience

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and non-thrombocytopenic purpura.

Gastrointenstinal: Mesenteric arterial thrombosis; ischemic colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

OVERDOSAGE
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

Excessive Bradycardia: administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure: digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

Hypotension: administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a $beta_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ≥ 80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 5 mg b.i.d. alone or in combination with other antihypertensive agents. An antihypertensive response usually occurs within the first week of treatment. Maximal response, however, may take as long as or occasionally longer than two weeks. If a satisfactory reduction in blood pressure does not occur within 3-4 weeks, the dose may be adjusted in increments of 10 mg per day at these intervals up to a maximum of 60 mg per day.

HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05).

UNIWEAVE™
The Better Direction in Angiography Catheters.
American Edwards Laboratories created Uniweave to meet your needs for a low-mass woven catheter that also delivers the high flow rate and torque control you demand.
We began by pioneering our revolutionary Uniweave™ construction process. Then we extended overall catheter design to new levels of precision and strength.
The end product, Uniweave catheters: different from the inside out. And better all the way around.

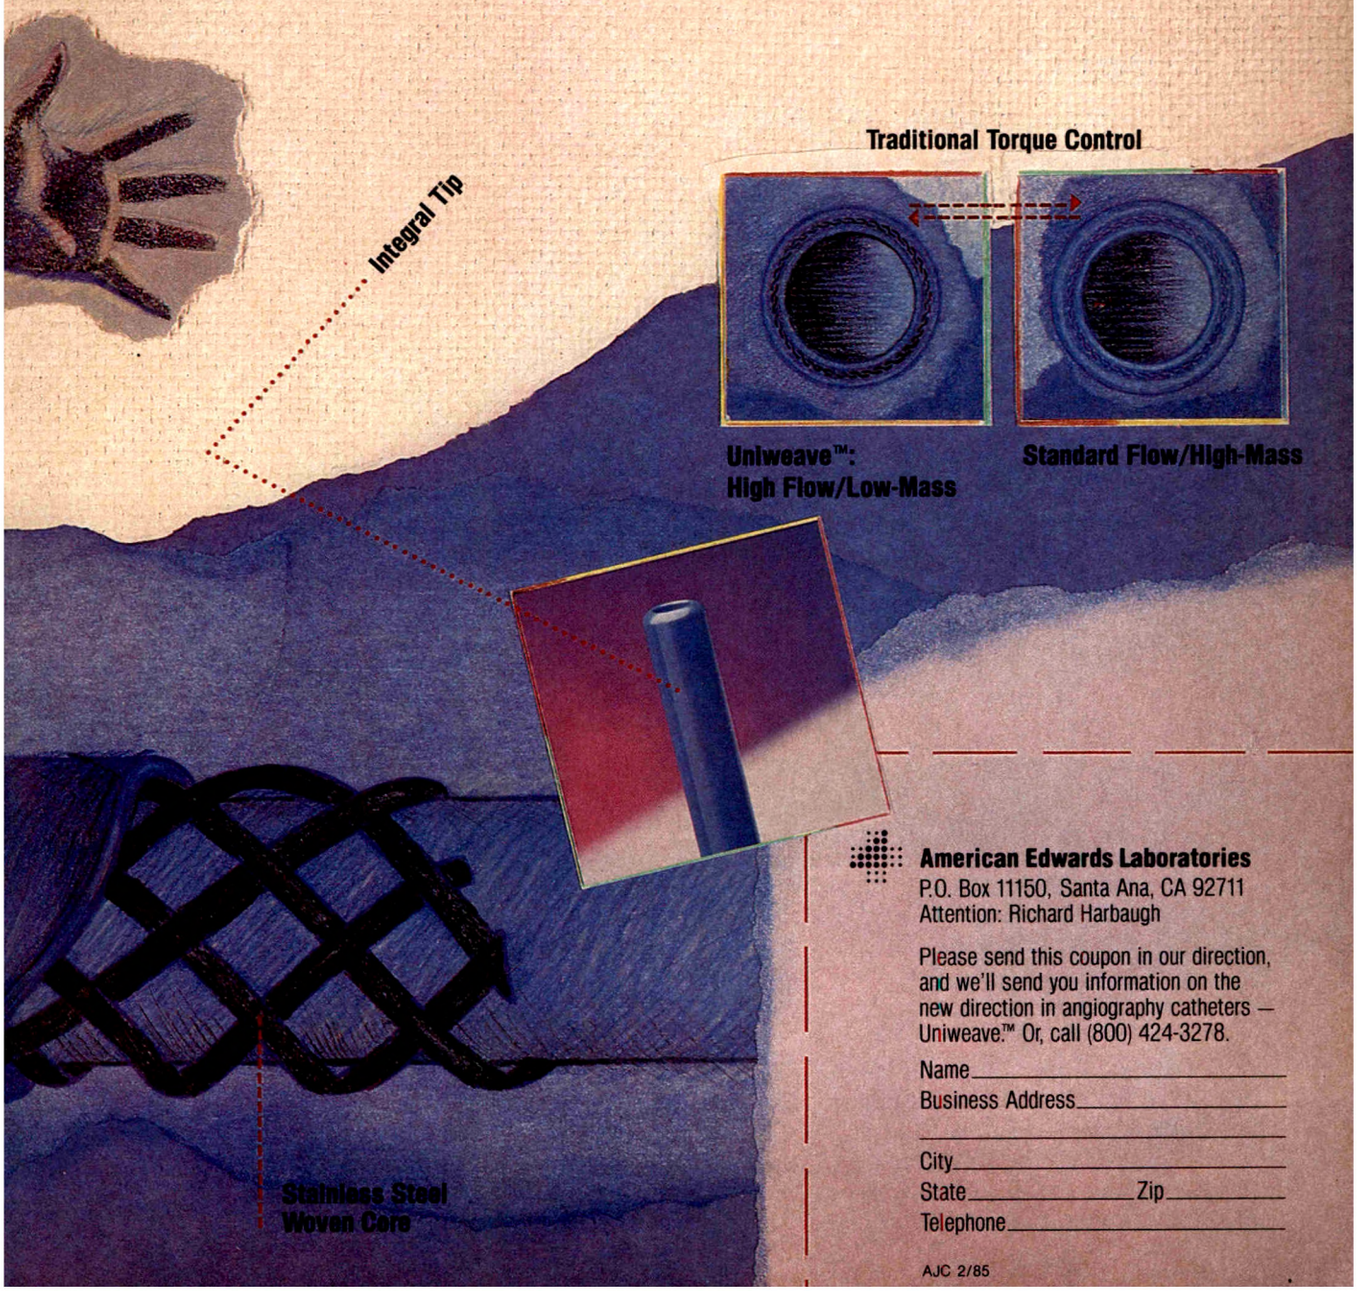
Uniweave. The better direction in construction.
Uniweave construction makes the stainless steel woven core an integral part of the polyethylene catheter wall. The result is enhanced wall strength with traditional control in a smaller French size catheter.

Unibody design. The better direction in patient safety.
Thanks to Uniweave construction, the tip of the catheter is also an integral part of the catheter wall. So, unlike the two-piece welded-on separate tips of competitive catheters, a Uniweave tip can never come off. Uniweave tips also have an unsurpassed shape consistency.

The better direction in high flow through a low-mass catheter.
The inside dimension of a catheter determines potential flow rate. The outside dimension dictates the access size.

Uniweave delivers the flow you need through an exceptionally strong, low-mass catheter.

The first step in the future direction of angiography.
We believe Uniweave angiography catheters will bring the option of out-patient angiography a step closer to reality. Our low-mass design means Uniweave requires a smaller access site — decreasing the possibilities of post-procedural bleeding.



American Edwards Laboratories
P.O. Box 11150, Santa Ana, CA 92711
Attention: Richard Harbaugh

Please send this coupon in our direction, and we'll send you information on the new direction in angiography catheters — Uniweave.™ Or, call (800) 424-3278.

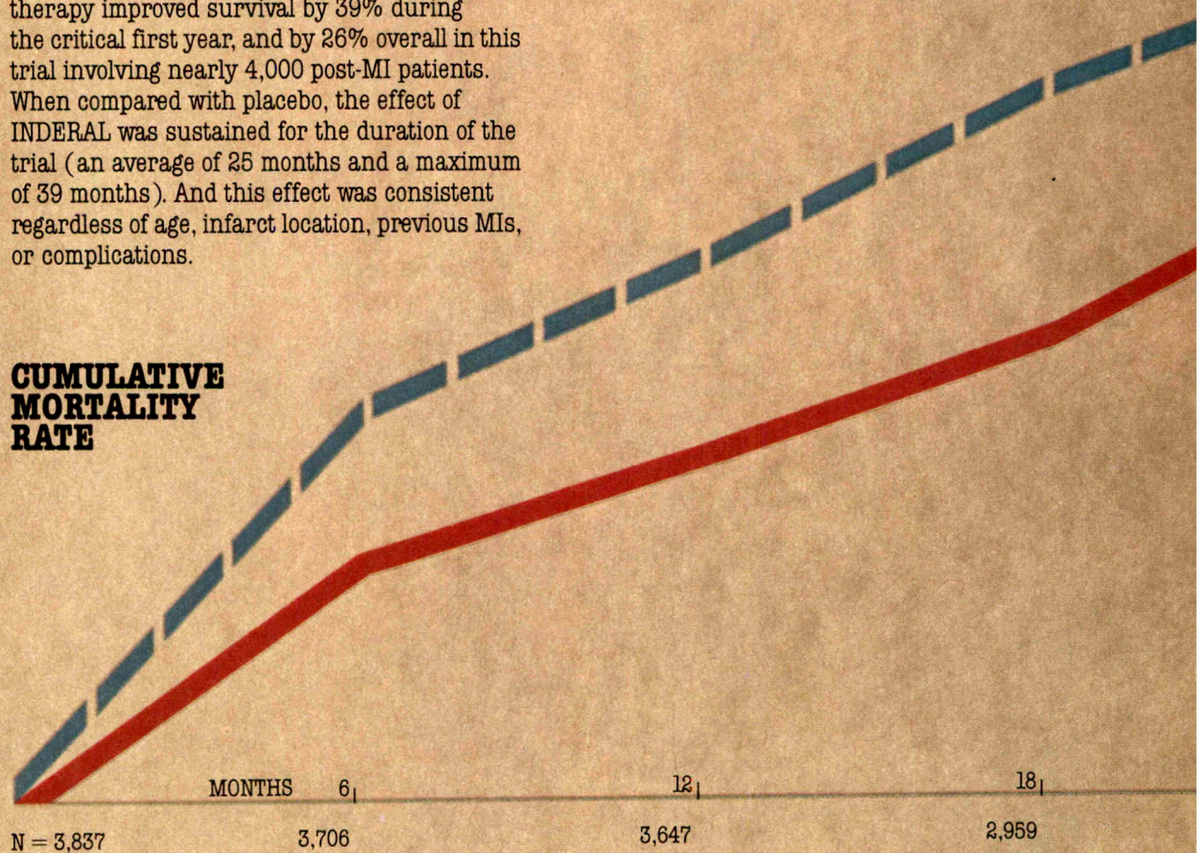
INDERAL® (PROPRANOLOL HCl) MAKES A CRITICAL DIFFERENCE, POST-MI

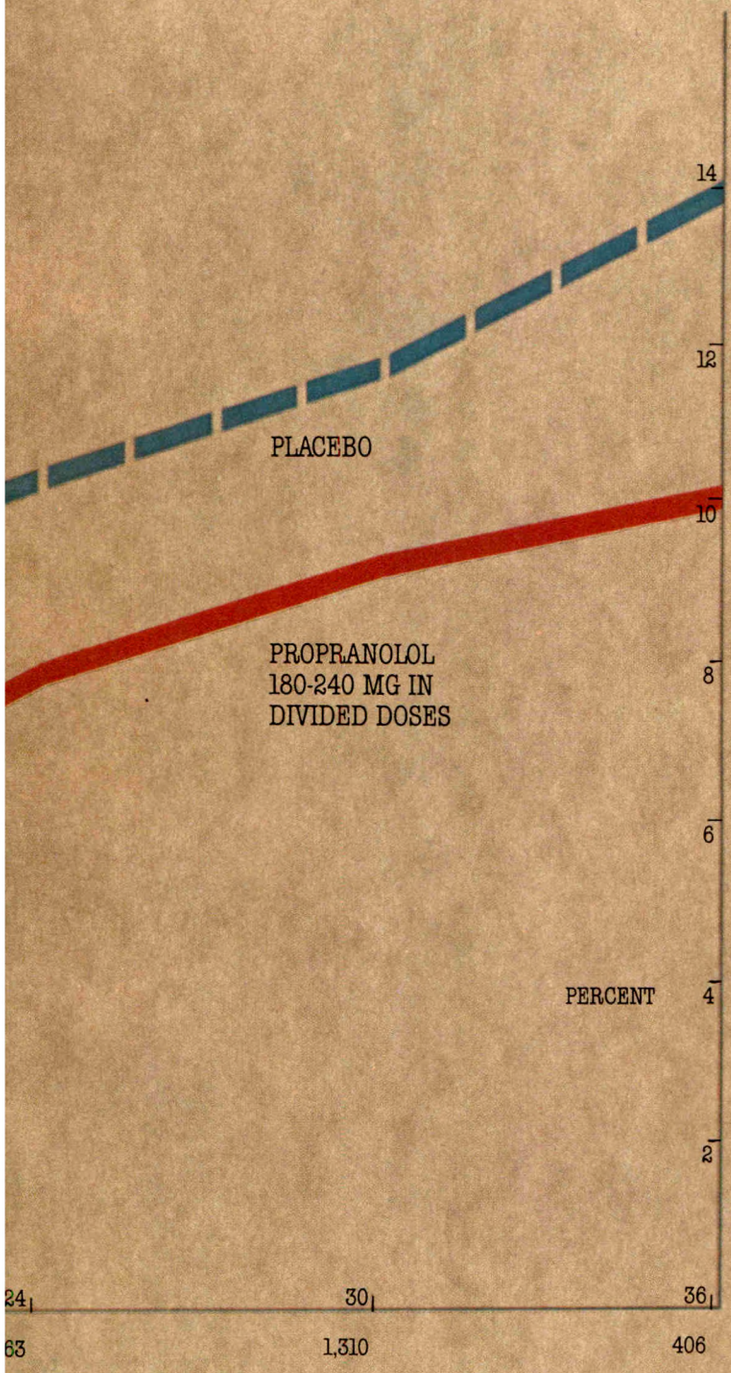
THE AMERICAN HEART ATTACK TRIAL PROVES INDERAL HAS THE POTENTIAL TO SAVE LIVES*

INDERAL significantly improves post-MI survival. This has not been proven for all beta blockers.

Only INDERAL has proven, in a major U.S. heart attack trial, that it can save lives. INDERAL therapy improved survival by 39% during the critical first year, and by 26% overall in this trial involving nearly 4,000 post-MI patients. When compared with placebo, the effect of INDERAL was sustained for the duration of the trial (an average of 25 months and a maximum of 39 months). And this effect was consistent regardless of age, infarct location, previous MIs, or complications.



*All study findings are excerpted from β-Blocker Heart Attack Trial Research Group: A randomized trial of propranolol in patients with acute myocardial infarction. I. Mortality results. *JAMA* 1982;247:1707-1714.



WITH ITS FAVORABLE SIDE EFFECTS PROFILE–INVESTIGATORS RECOMMEND INDERAL THERAPY FOR AT LEAST 3 YEARS POST-MI†

The study participants, who represented a wide range of risk categories as seen in today's practice, began therapy 5 to 21 days after the infarction, once clinically stable. The dosage was 180 to 240 mg per day. At this appropriate dosage level, INDERAL was well tolerated even in the high-risk population of patients. Incidence of patient complaints on propranolol was similar to complaints on placebo, and consistent with those generally reported with the use of INDERAL. †INDERAL should not be used in the presence of congestive heart failure, heart block greater than first degree, bronchial asthma, and cardiogenic shock.

INDERAL IS THE ONLY BETA BLOCKER INDICATED FOR HYPERTENSION, ANGINA, ARRHYTHMIA, AND POST-MI

Lifesaving potential that rarely interferes with everyday living...the critical difference that INDERAL makes, post-MI.

(PROPRANOLOL HCl)

THE POTENTIAL TO SAVE LIVES

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)

INDERAL® (propranolol hydrochloride) Tablets

CLINICAL PHARMACOLOGY

The Beta-Blocker Heart Attack Trial (BHAT) was a National Heart, Lung and Blood Institute-sponsored multicenter, randomized, double-blind placebo-controlled trial conducted in 31 U.S. centers (plus one in Canada) in 3,837 persons without history of severe congestive heart failure or presence of recent heart failure; certain conduction defects; angina since infarction, who had survived the acute phase of myocardial infarction. Propranolol was administered at either 60 or 80 mg t.i.d. based on blood levels achieved during an initial trial of 40 mg t.i.d. Therapy with INDERAL, begun 5-21 days following infarction, was shown to reduce overall mortality up to 39 months, the longest period of follow-up. This was primarily attributable to a reduction in cardiovascular mortality. The protective effect of INDERAL was consistent regardless of age, sex or site of infarction. Compared to placebo, total mortality was reduced 39% at 12 months and 26% over an average follow-up period of 25 months. The Norwegian Multicenter Trial in which propranolol was administered at 40 mg q.i.d. gave overall results which support the findings in the BHAT.

Although the clinical trials used either t.i.d. or q.i.d. dosing, clinical, pharmacologic and pharmacokinetic data provide a reasonable basis for concluding that b.i.d. dosing with propranolol should be adequate in the treatment of post-infarction patients.

CLINICAL: In the BHAT, patients on INDERAL were prescribed either 180 mg/day (82% of patients) or 240 mg/day (18% of patients). Patients were instructed to take the medication 3 times a day at mealtimes. This dosing schedule would result in an overnight dosing interval of 12 to 14 hours which is similar to the dosing interval for a b.i.d. regimen. In addition, blood samples were drawn at various times and analyzed for propranolol. When the patients were grouped into tertiles based on the blood levels observed and the mortality in the upper and lower tertiles were compared, there was no evidence that blood levels affected mortality.

PHARMACOLOGIC: Studies in normal volunteers have shown that a 90 mg b.i.d. regimen maintains beta blockade at, or above, the minimum for 60 mg t.i.d. dosing for 24 hours even though differences occurred at two time intervals. At 10-12 hours after the first dose of the day, t.i.d. dosing gave more beta blockade than b.i.d. dosing; at 20-24 hours the trend of the relationship was reversed. These relationships were similar in direction to those observed for plasma propranolol levels (see Pharmacokinetic).

PHARMACOKINETIC: A bioavailability study in normal volunteers showed that the blood levels produced by 180 mg/day given b.i.d. are below those provided by the same daily dosage given t.i.d. at 10-12 hours after the first dose of the day but above those of a t.i.d. regimen at 20-24 hours. However, the blood levels produced by b.i.d. dosing were always equivalent to or above the minimum for t.i.d. dosing throughout the 24 hours. In addition, the mean AUC on the fourth day for the b.i.d. regimen was about 17% greater than for the t.i.d. regimen (1,194 *vs.* 1,024 ng/ml• hr).

CONTRAINDICATIONS

INDERAL is contraindicated in 1) cardiogenic shock, 2) sinus bradycardia and greater than first degree block, 3) bronchial asthma, 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL (propranolol hydrochloride) should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS

General: Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: Lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

Value of Multiple Echocardiographic Views in the Evaluation of Aortic Stenosis in Adults by Continuous-Wave Doppler

GEORGE A. WILLIAMS, MD, ARTHUR J. LABOVITZ, MD, JEANNE G. NELSON, and HAROLD L. KENNEDY, MD

Fifty-two adults referred for evaluation of aortic stenosis (AS) were studied using continuous-wave and pulsed Doppler echocardiography. Three windows were used to determine which approach (apical, right parasternal or suprasternal) yielded optimal results. Doppler-derived peak aortic valve gradients were compared with the peak gradients measured at cardiac catheterization in 23 patients. High-velocity jets were best recorded from the cardiac apex and less frequently from the right parasternal and suprasternal areas. However, gradients from the right parasternal area correlated best with cardiac catheterization findings, although recordings could be made from this window in only 49% of the patients. Velocities from the suprasternal window were significantly ($p < 0.01$) lower than those from the apex or right parasternal areas. Gradient underestimation from the suprasternal window tended to increase with age of the patient ($p < 0.1$). When the maximal Doppler derived gradient from any window was compared with catheterization measurements, the correlation coefficient was 0.86. Gradients derived from Doppler velocities accurately predicted severe (more than 50 mm Hg) gradients at catheterization. Thus, Doppler echocardiography is useful in evaluation of AS when several windows are used for optimal assessment of aortic valve gradient.

(Am J Cardiol 1985;55:445–449)

Doppler echocardiography is a valuable adjunct to the noninvasive evaluation of aortic valve stenosis (AS). Before Doppler techniques were introduced, approaches to AS quantitation using echocardiography[1–3] were limited to describing deformity and calcification. Pulsed Doppler added initial quantitative information through its ability to document and quantitate the extent of disturbed flow distal to the lesion.[4,5] Continuous-wave Doppler allowed measurement of the transvalvular gradient.[6–8] Since not all patients can be examined from any 1 window,[6,9,10] Doppler recordings have been made from multiple windows.[6,8] In young patients the supravalvular windows were the most reliable,[6] but not in older patients.[9,10] We investigated the value of 3 windows (apical, right parasternal and suprasternal notch) in older patients with acquired AS, the relation of age to the adequacy of each window, and the use of all 3 windows in each patient to improve localization and quantitation of abnormal signals.

Methods

Between November 1982 and July 1983, 52 patients (30 men, 22 women) referred for AS were examined with Doppler echocardiography. Only patients with echocardiograms that showed aortic valvular thickening or calcific deposits and reduced mobility were selected. Patients with congestive heart failure, moderate to severe aortic regurgitation by physical examination, or more than grade 1/6 aortic regurgitation at catheterization were excluded. The mean age was 63 years (range 20 to 82); 2 patients were 40 years old.

Twenty-three patients had aortic valve gradients detected at cardiac catheterization. Doppler was performed in a blinded fashion within 24 hours after cardiac catheterization in 19 patients, within 1 week before catheterization 3 patients, and at 1 year in a patient with mild congenital AS and no signs of progression of AS.

Doppler technique: The Irex System IIIB or Exemplar were used to record Doppler signals. Pulsed and continuous-wave Doppler were recorded with simultaneous 2-dimensional imaging using a 2.5 or 3.5-MHz imaging and 2.0-MHz Doppler frequency. A 2.0-MHz nonimaging Doppler trans-

ducer was used when weak signals were recorded with simultaneous imaging. Pulsed Doppler was used with simultaneous imaging in an apical 5-chamber view to identify the source of high-velocity signals as being the aortic valve area. Continuous-wave Doppler interrogation of the entire depth of the heart detected the highest possible velocities at each area. Two criteria were used to assess angulation of the Doppler beam with the high-velocity jet in the continuous mode. First, the beam was assumed to be parallel to the high-velocity jet when the velocities were highest on the Doppler spectral tracing. Second, the interrogating beam was assumed to be adequately aligned with the jet when the spectral tracing of the Doppler output revealed a maximal concentration of high velocity signals outlining the tracing with few low velocity signals (Fig. 1) and a clear pitch was heard from the auditory output.

Three windows were evaluated: left ventricular apex at or near the point of maximal impulse, the right parasternal area at the second to fourth interspace, and the suprasternal notch. The aortic transvalvular gradient was estimated by the modified Bernoulli formula[11]: $P = 4(V_2^2 - V_1^2)$, where V_2 represents the jet velocity and V_1 the left ventricular outflow tract velocity. When V_1 is less than 1 m/s, the transvalvular pressure estimate changes less than 4 mm Hg, and the gradient was calculated from the highest velocity from any site as $P = 4(V\ max)^2$. Normal aortic velocities were assumed to represent the lack of a transvalvular gradient.

Cardiac catheterization was performed in 23 patients. Pressure gradients were recorded from fluid-filled endhole catheters using either a slow pullback from left ventricle to aorta or simultaneously from left ventricle and femoral artery through a sidearm sheath. In the latter case, the gradient was corrected for any aortofemoral systolic pressure difference. The peak-to-peak catheterization gradient was compared to the Doppler gradient by linear regression analysis.

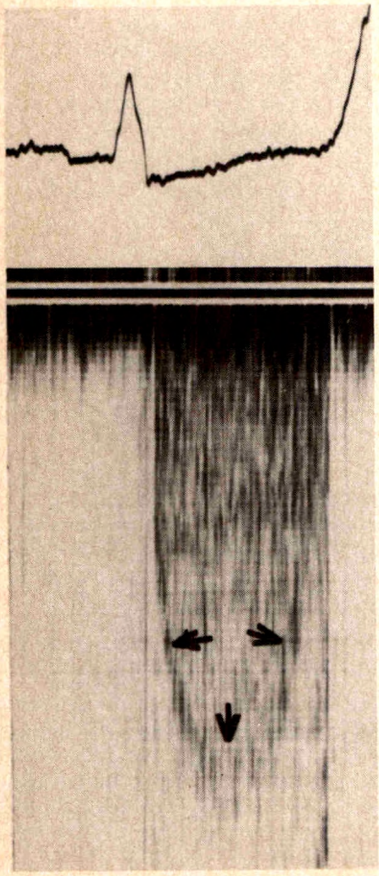

FIGURE 1. Isolated flow velocity profile shows characteristics of an adequately aligned Doppler beam. A high concentration (**dark outline**) of high-velocity reflectors surrounds the trace (**arrows**) with relatively fewer low velocity reflectors within the borders of the tracing.

Results

Technically adequate tracings were obtained from at least 1 viewing window in 51 of 52 patients (98%). Stronger signals and higher velocity tracings were produced by the independent transducer in 47 of the 52 patients (90%). Doppler gradients ranged from 0 to 136 mm Hg.

The apical 5-chamber view was the easiest to record. Aortic jet velocities were recorded in 47 of 52 patients (90%). In 6 patients the velocities could only be recorded from the apex. Calculated gradients from the apex ranged from 0 to 136 mm Hg. In 38 patients, velocities recorded from the apex equaled or exceeded those recorded from the other areas. Left ventricular outflow tract velocities were recorded from the apex in all patients and aortic insufficiency was detected by Doppler in 18 patients (35%). It was clinically unsuspected in 17. In 8 of the patients with aortic insufficiency by Doppler, the diagnosis was confirmed at cardiac catheterization.

The right parasternal view was the most difficult to record, requiring angulation of the transducer from the third, fourth or fifth intercostal spaces to adequately record high-velocity jets. Appropriately oriented jet recordings were possible in 25 of the patients (49%). Right parasternal area velocities were the highest recorded from any window in 6 patients and equaled maximal velocities from other areas in 3 other patients. In 1 study the right parasternal area was the only view available.

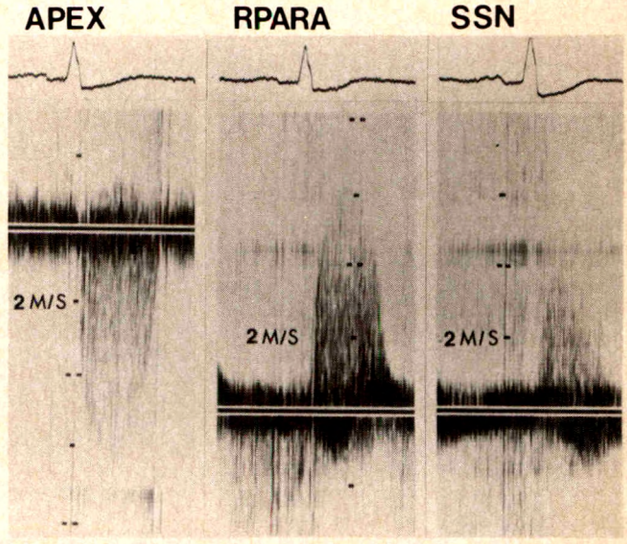

FIGURE 2. Doppler recordings from 3 areas in 1 patient. The profile at the apex reveals a sharp border and a peak velocity of 6.0 m/s. At the right parasternal area (RPARA), a similar velocity is seen but the outline is less well defined. At the suprasternal notch (SSN), a lower velocity and less well defined outline are present.

Suprasternal notch blood flow recordings could be made in 35 of the patients (69%). In 2 cases the suprasternal notch was the only view that could be recorded. Measured velocities were usually lower than those from the other 2 areas, being equal to or greater than the velocities from the other areas in only 4 of 51 patients (8%).

Representative tracings from each area are shown in Figure 2. The apical velocity curve reveals a well outlined tracing with a maximal velocity of approximately 6 m/s. A similar velocity is seen from the right parasternal area; however, the outline is less well defined than that of the apical tracing. The suprasternal notch tracing lacks a well defined outline and the measured velocity is lower than that seen from the other 2 areas. Velocities from the apex (3.6 ± 1.1 m/s) and right parasternal area (3.5 ± 1.0 m/s) were similar (Fig. 3). Suprasternal notch velocities (2.3 ± 0.9 m/s) were significantly ($p < 0.001$) lower than those of the other 2 areas.

The underestimation of aortic velocity from the suprasternal notch tended to increase with age. When suprasternal notch velocities were compared with maximal velocity the mean underestimation was 19% in patients between 40 and 60 and 31% in those over 60 years old ($p < 0.1$).

Catheterization-Doppler correlation: Aortic valve gradients at catheterization ranged from 0 to 125 mm Hg. The correlation between catheterization and Doppler gradients was good (Fig. 4). In 1 patient, despite an adequate tracing, the catheterization gradient was underestimated by 66 mm Hg (74 vs 140 mm Hg).

When a 50-mm Hg gradient was used to separate severe from less severe AS, Doppler accurately identified 11 of 12 patients with gradients less than 50 mm Hg. There were no patients who had a catheterization gradient greater than 50 mm Hg classified as having a lower gradient by Doppler.

In 10 of the 12 patients with catheterization gradient less than 50 mm Hg Doppler overestimated the gradient by 2 to 25 mm Hg (mean 10). Examination of instantaneous gradients in the patient with the greatest disparity revealed the maximal instantaneous Doppler gradient (36 mm) at 200 ms after the QRS, and the peak to peak gradient from catheterization (20 mm) at 320 ms after the QRS. As a result, a disparity of 16 mm Hg was present between the maximal instantaneous Doppler gradient and peak to peak pressure gradient.

Twenty-one patients who underwent catheterization had adequate recordings from the left ventricular apex, with a correlation value of 0.88 between calculated and catheterization gradients (Fig. 5). Only 9 patients could be examined from the right parasternal area. The Doppler results closely correlated with catheterization results ($r = 0.93$). At the suprasternal notch, patients had adequate tracings. In 3 of the 15 the gradient was underestimated by 10 mm Hg or more compared with catheterization ($r = 0.79$).

Discussion

The use of Doppler ultrasound to quantitatively evaluate AS gradients requires proper sampling and recording technique and the ability to record high velocity flows accurately. In this study continuous-wave Doppler provided several advantages. Continuous-wave Doppler accurately measured high velocity. Scanning along the entire depth of the interrogating beam can improve localization of abnormal jets.[12] The accuracy of the Doppler technique depends on the ability to orient the sound beam parallel to the jet. Using continuous-wave Doppler and spectral tracings allowed estimation of the orientation of the jet and ultrasonic beam[7] by the presence of a higher-pitched audio signal and concentration of reflector density at the top of the spectral trace. This ability is particularly important in acquired AS. Under ideal conditions flow is assumed to be parallel to vessel walls and angle correction can be made visually. In a straight tube model, turbulent post–jet flow disturbance and distal relaminarization of flow have been demonstrated.[13] Although the jet may be parallel to vessel walls as in the straight tube model, in acquired AS the high-velocity jet is often eccentric because of valve deformity. As a result, it is important to estimate the angle of incidence of the jet and sound beam from the Doppler characteristics.

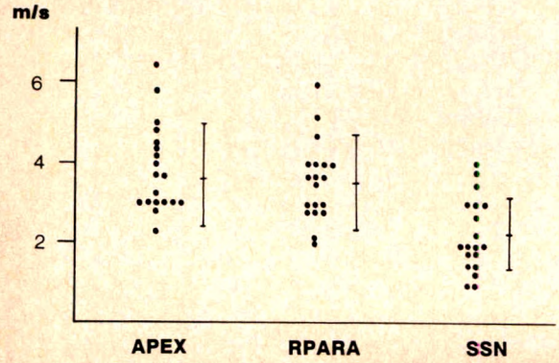

FIGURE 3. The maximal velocities from the apex, right parasternal area (RPARA), and suprasternal notch (SSN) for 19 patients.

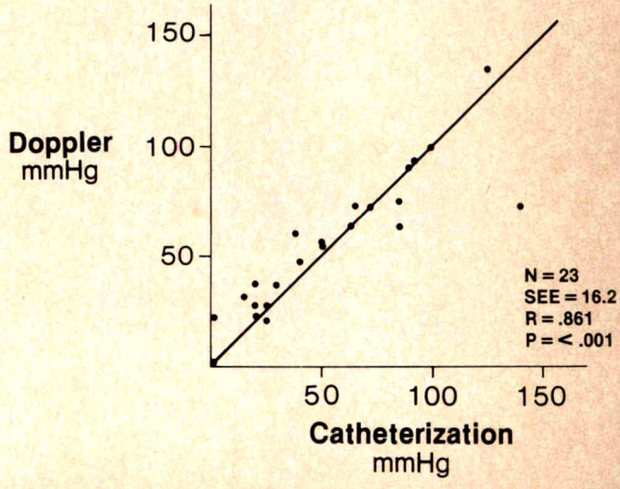

FIGURE 4. Aortic peak gradient obtained at cardiac catheterization and that calculated from Doppler tracing in 23 patients. In 22 patients a close relation to the line of identity is present. In 1 patient a significant underestimation occurs, possibly secondary to angulation.

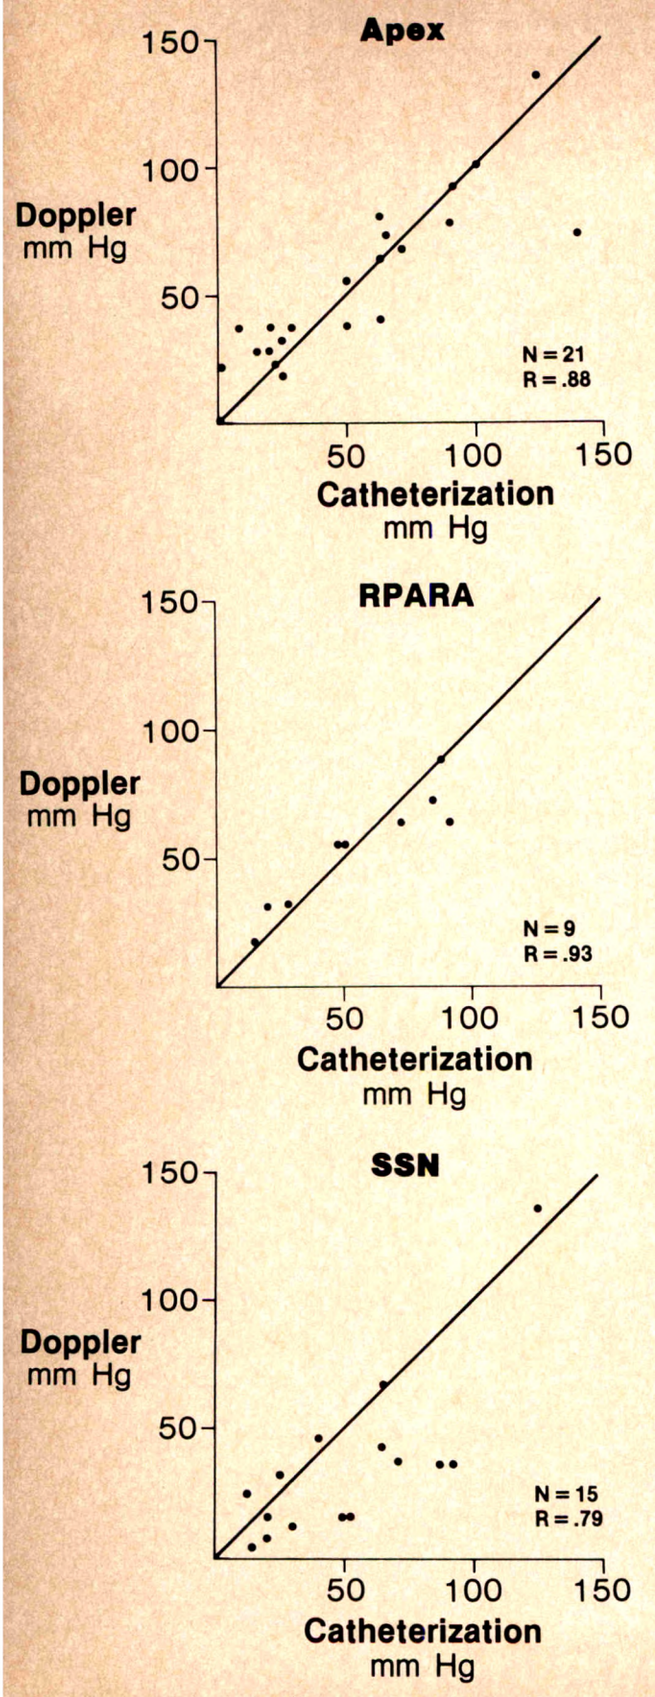

FIGURE 5. Comparison of catheterization gradient with Doppler calculated gradient obtained from each area. The correlation was 0.88 for the cardiac apex (**top**), 0.93 for the right parasternal area (RPARA) (**middle**) and 0.79 for the suprasternal notch (SSN) (**bottom**).

Continuous-wave Doppler cannot localize the site of obstruction, showing all velocities along the interrogating beam. Thus, pulsed Doppler with simultaneous imaging was used to localize the jet to the aortic valve.

The use of multiple sampling sites has been recommended,[6,7] but the reliability of multiple sites has not been compared in adults. In a group of younger patients with valvular AS,[6] the supravalvular areas provided better correlation with measured gradients than the apical area. Similar results were found by Stamm and Martin.[8] Others[9,10] have used only supravalvular views for evaluating AS. These studies, using a combination of suprasternal and right or left parasternal areas, found correlation with catheter gradients of 0.85 and 0.86 respectively. However, in one of the studies[10] 2 patients with catheterization gradients greater than 50 mm Hg were not recognized by Doppler and 4 of 35 patients had inadequate signals from these windows. In the present study, 51 of 52 patients (98%) had adequate tracings. The right parasternal area provided calculated gradients closest to those of cardiac catheterization, as in the study of Hatle,[6] but the low success rate of recording velocities at this site (49%) is similar to others.[7] In this study the suprasternal notch view, although easier to record than the right parasternal area, had significantly lower ($p < 0.001$) recorded velocities. The most likely explanation for this finding lies in the ages of our patients. Only 7 patients were younger than 60 years; the rest were 60 to 82 years old. Underestimation tended to increase with age in this group, although not enough patients under 60 years old were present to achieve statistical significance. Although the continuous-wave Doppler can penetrate to the aortic valve level, the jet from the valve may be oriented at an angle to the Doppler beam due to valve deformity and ectasia of the aorta present in older patients. Since the Doppler shift is inversely proportional to the cosine of the angle of the intercept of the flow vector and the beam, the resultant calculated velocity will be lower. In the present study the Doppler signals were most readily obtained from the apex and tended to produce velocities equal to or higher than those from the other views. The apical view also allowed scanning of the left ventricular outflow tract with pulsed Doppler to localize the site of obstruction.[4]

In our cases of mild AS with normal left ventricles, overestimation of the valve gradient was present in 10 of 12 patients. Although the mean overestimation was low, in 4 patients it exceeded 10 mm Hg. The explanation for this overestimation lies in the difference of measurement technique between echocardiography and catheterization. Doppler jet velocities estimate the maximal instantaneous pressure difference between the left ventricle and aorta, which occurs early in systole in mild AS. The peak-to-peak pressure gradient drop measured at catheterization occurs later in systole and is lower than the maximal systolic gradient.

The major impact of our findings is that hemodynamically important AS (pressure drop more than 50 mm Hg) can be separated from less severe stenosis in 98% of patients when 3 windows are used. All patients in this study had normal left ventricular function by

2-dimensional echocardiography. Doppler pressure gradients must be interpreted taking into account left ventricular function. The jet velocities are related only to the pressure gradient, and both pressure and velocity decrease with left ventricular failure.

Coronary Artery Luminal Diameter in Aortic Stenosis

SULTAN A. ABDULALI, MD, B. GANESH BALIGA, MD,
ANDREW D. CLAYDEN, BS, PhD, LIMA,
and DONALD R. SMITH, MD

The coronary artery luminal diameters in 32 patients with aortic stenosis (AS) were compared with those of 24 control subjects without left ventricular (LV) hypertrophy by means of a derived index. Patients with AS had significantly larger coronary arteries than the control subjects ($p < 0.01$). The increase in coronary luminal diameter had a weak correlation to LV wall thickness ($r = 0.32$) and LV mass ($r = 0.34$). Among 21 patients with AS and normal coronary angiograms, those with angina had higher peak LV pressures (224 ± 8 vs 196 ± 7 mm Hg) and greater peak systolic gradients (103 ± 9 vs 74 ± 10 mm Hg) than those without angina ($p < 0.05$). However, there was no significant difference in coronary artery diameters, peak LV stress or LV tension at rest between patients with and without angina.

(Am J Cardiol 1985;55:450–453)

Patients with aortic stenosis (AS) have as much as a 3-fold increase in left ventricular (LV) mass.[1] Physiologic studies in patients with AS have shown that at rest, blood flow per gram in the left ventricle is normal.[2–4] To maintain this normal flow to the hypertrophied left ventricle, coronary artery size must increase concomitantly. Inadequate growth of the large epicardial vessels in hearts with severe LV hypertrophy has been reported.[5,6] Marcus et al[7] speculated that inadequate growth of the microcirculation may be the mechanism of the reduced coronary reserve in patients with AS and angina who do not have coronary artery disease.[7] This study examines coronary arterial size during LV coronary and angiography in patients with AS and LV hypertrophy compared with that in "normal" control subjects and assesses whether coronary artery size correlates with any LV hemodynamic measurements or with the presence or absence of angina in the absence of coronary artery disease.

Methods

Patients: The cardiac catheterization data and LV coronary angiograms of all patients with pure AS investigated in our department from 1979 through 1983 were reviewed. Thirty-two patients who had satisfactory angiograms that allowed accurate measurement of LV variables and coronary artery size were identified. Their clinical notes were then reviewed and they were subclassified according to the presence or absence of angina pectoris. Twenty patients had a history of angina (Table I).

The 24 patients in the control group were investigated for atypical chest pain and had normal coronary angiograms. They had normal electrocardiograms at rest and negative or indeterminate exercise tests. They were diagnosed as having noncardiac chest pain (Table I).

Cardiac catheterization technique: All treatment was stopped 12 hours before the examination. After an overnight fast, 10 mg of diazepam was administered orally as premedication. Standard left-sided (and right-sided, if necessary) cardiac catheterization was carried out in the supine position. All patients with AS underwent LV catheterization by the transseptal route. The LV angiogram was performed in the right anterior oblique projection using 50 ml of Urografin-370® injected by a pump at a rate of 12 ml/s. Coronary arteriograms were performed by the Judkins technique using 10 to 12 ml of the same contrast given by hand injection for each projection. An 8Fr gauge catheter was used for right and left coronary arteries for all coronary angiograms. A cine film strip of an area determination grid (Namic) was routinely taken at the end of each investigation at the estimated distance of the left ventricle (10 cm above the table) from the camera for each patient.

Determination of coronary artery luminal index and left ventricular variables: The index of coronary luminal diameter was determined as follows. The coronary angiogram was projected on to a white screen and the presence or absence of any coronary artery narrowing was noted. Severity of any stenosis was assessed visually. Significant disease was defined as luminal narrowing of a major vessel by 70% or more in any projection. Frames of the angiogram that showed clearly the

CAD = coronary artery disease.

coronary catheter together with the major coronary arteries (left anterior descending, the left circumflex and right coronary arteries) in end-diastole were identified and used for measurements. With a mathematical caliper the diameter of each of the major coronary arteries was measured in millimeters immediately after their origin and before any further branches had been given off. Measurements were made in 3 projections for the 2 left coronary artery branches and in 2 projections for the right coronary artery. In each projection the diameter of the shaft of the coronary catheter was similarly measured at a point immediately before the beginning of the tapering of the tip. The index of coronary luminal diameters was determined by taking the mean value of the ratios of coronary artery diameter to that of the catheter. As the same size catheter (8Fr) was used in all patients, the index derived in this way discounts variation in magnification between patients and projections, allowing comparison of the coronary luminal diameter between groups.

The LV angiograms were projected on a white sheet of paper and the cardiac cycle for volume and mass determination selected. Care was taken to avoid a cycle that occurred during or after an extrasystole. The LV outline was traced at end-systole and end-diastole. The LV wall thickness measurement was made at end-diastole at a point midway between the aortic valve and the apex. The film strip of the area determination grid (which was 1-cm^2 grid marks) was projected over the LV trace to obtain the correction factor for magnification. A graphics analyzer, model 1239 (Numonics), was used to measure LV volumes and wall thickness for the derivation of LV mass. This uses the area-length method described by Dodge[8] for the right anterior oblique projection (regression equation: $V' = 81V + 1.9$).

Peak LV equatorial wall stress was calculated using the thick wall ellipsoid formula of Falsetti et al,[9] which assumes uniform distribution of stress across the LV wall and peak LV tension by the method of Sandler and Dodge.[10]

Certain assumptions are made in the aforementioned calculations: The LV volume and mass calculations are based on the 1-plane data of Sandler and Dodge[11] which assumes the left ventricle to be an ellipsoid, thin-walled shell. The end-diastolic dimensions were used to measure peak LV wall stress. This assumes that dimensions do not change from end-diastole to peak stress and that maximal tensions occurred at time of peak LV pressure.[12] All groups were treated similarly; thus, the conditions should be valid.

Tests for statistical significance used in the analysis were the Wilcoxon test for unmatched data and the Pearson correlation coefficient.

Results

Eleven of the 32 patients (34%) with AS had significant coronary artery disease by angiography. Two of the patients (18%) with coronary artery disease gave no history of angina. All patients were in sinus rhythm.

Patients with AS had higher voltage in the LV leads of the electrocardiograph ($p < 0.01$), higher LV mass ($p < 0.01$), thicker LV walls ($p < 0.01$) and greater end-diastolic volumes ($p < 0.05$) than control subjects (Table II). There were no significant differences in ejection fractions between the 2 groups. The ejection fraction had a significant negative correlation with LV mass ($r = -0.52$, $p < 0.01$). Patients with AS had larger coronary arteries than control subjects (Fig. 1). There was weak correlation between coronary artery luminal diameter index and LV mass ($r = 0.34$). This also applied to the size of the left anterior descending artery when correlated with LV wall thickness ($r = 0.32$).

Patients with aortic stenosis and normal coronary arteries: There was no significant difference in coronary artery size between those with (11 patients) and those without angina (10 patients) (Fig. 2). Patients with angina had higher peak systolic gradients and peak LV pressure ($p < 0.05$). Other measurements, such as ejection fraction, LV end-diastolic pressure, LV end-diastolic volumes, LV mass, wall thickness, peak LV

Discussion

The mechanism of angina in patients with AS and normal coronary arteries has not been defined. An imbalance between coronary blood flow and the metabolic demand for oxygen in the hypertrophied left ventricle must exist.

Hemostatic mechanisms govern the regulation of phasic coronary flow. An anatomic limitation in blood supply as a result of inadequate growth of coronary vasculature, in response to the increase in LV mass in left ventricular hypertrophy, has been proposed as a mechanism of angina in these patients who do not have coronary artery disease.[5,7,14] Based on postmortem measurements of coronary ostial and epicardial vessel size, it was proposed that the limitation in growth of the large coronary vessels resulted in outstripping of the blood supply to the hypertrophied myocardium causing ischemia.[5,13,14] Our study shows that there is no difference in the size of epicardial vessels in patients with and those without angina and that, in the living subject, there is poor correlation between coronary artery size and LV mass or wall thickness, despite a significant increase in luminal diameter with myocardial hypertrophy.

Studies after stress induced by isoproterenol,[3] atrial pacing[4] and coronary occlusion[7] all show that patients with AS and angina who do not have coronary artery disease have a greater reduction in coronary reserve than those without angina and without coronary artery disease. Impaired vasodilator responses in response to exercise have been demonstrated in animals with LV hypertrophy.[15,16] Epicardial vessels contribute minimally to coronary vascular resistance[17] and are unlikely to be responsible for these vasodilator responses. However, if the growth of coronary microcirculation in the hypertrophied left ventricle did not keep pace with the increase in LV mass in the presence of normal flow, minimal coronary vascular resistance would increase and, thus, limit coronary vasodilator responses in the hypertrophied ventricle.[7,15] At rest, there was no ob-

served difference in our patient with regard to the size of the large coronary arteries in AS patients with and without angina. Do the small resistance vessels behave differently? We argue that the proposed inadequate growth of the coronary microcirculation probably does not account for the mechanism of angina on its own. Other factors probably play a part. During exercise there is an increase in LV ejection period and a reduction in diastolic period of nutrient flow associated with an increase in heart rate. Our AS patients with angina and normal coronary arteries had higher peak LV pressures and peak systolic gradients than those without angina, a finding reported by others.[18] These greater pressures would result in greater extravascular compression of intramural vessels augmenting any abnormality of coronary flow and restricting vasodilation during exercise in patients with angina.

Myocardial oxygen consumption is determined by contractility[19] and LV wall tension.[20] The former is difficult to measure; the latter is determined by the stress the left ventricle is subjected to. The measurement of both these variables in our AS patients, with and without angina, were not significantly different. This finding is not surprising, however, because these data deal with the left ventricle as a whole rather than the distribution of forces across the LV wall. Differential distribution of intramural forces resulting in redistribution of blood flow from the subendocardium to the subepicardium has been put forward as a likely contributor to angina in AS.[3,4,21] This finding is supported by the fact that the ratio of diastolic pressure-time index to systolic pressure-time index is abnormal during exercise in the presence of normal coronary sinus oxygen saturation and coronary sinus blood flow.[21]

Detailed Anatomy of the Normally Functioning Aortic Valve in Hearts of Normal and Increased Weight

MARC A. SILVER, MD, and WILLIAM C. ROBERTS, MD

The area, weight and 4 linear variables were measured in each aortic valve cusp in 100 necropsy patients with normally functioning aortic valves, and the volume of each sinus of Valsalva and the aortic area at the sinotubular junction were determined in the same patients. The sums of the aortic valve cuspal areas, cuspal weights and sinus of Valsalva volumes increased with age ($p < 0.001$) and with heart weight ($p < 0.001$). All 3 variables (cuspal area, cuspal weight and sinus of Valsalva volume) also increased with age and heart weight relative to each other. The luminal area of aorta at the sinotubular junction also increased with age and heart weight and it also increased as the sum of the aortic valve cuspal areas and weights and sinus of Valsalva volumes increased. In only 16% of the 100 patients were the 3 aortic valve cusps of similar size (less than 5% difference in area between cusps); in 51%, 1 cusp was of different size than the other 2, and in 33% of patients all 3 cusps were of different sizes.

(Am J Cardiol 1985;55:454–461)

Although various features of dysfunctioning human aortic valves have been described, few reports are available describing results of detailed measurements of normally functioning human aortic valves. This report describes results of measuring at necropsy various dimensions of each aortic valve cusp, the volume of each sinus of Valsalva, and the luminal area of aorta at the sinotubular junction in 100 patients with normally functioning aortic valves.

Definitions

A *normal valve* may be defined as a thin, mobile layer of tissue located in a canal or passage, and this tissue allows free flow through the passageway and prevents reflux of the contents passing by it. When this definition of "valve" is applied to the normal aortic valve, it is applicable only to the 3 cusps (or leaflets). If the 3 aortic valve cusps are excised, an aortic valve is no longer present. Thus, the aortic valve is a structure located between left ventricular outflow tract and the tubular portion of aorta and within the sinus portion of aorta, and it consists of 3 freely mobile cusps. Although they affect both structure and function of the 3 aortic valve cusps, the structures contacted by the aortic valve cusps are not considered part of the aortic valve. The 3 aortic valve cusps are designated right, left and posterior. The term "non-coronary cusp" is best avoided because a coronary artery may originate from the wall of aorta behind the posterior cusp or a coronary ostium may be absent from 1 or both anteriorly located cusps.

A *sinus of Valsalva* is a space that exists between the aortic surface of an aortic valve cusp and the wall of aorta behind that cusp (Fig. 1). It is bounded caudally by the basal attachment of the aortic cusp (to wall of aorta, membraneous or muscular ventricular septum or anterior mitral leaflet) and above by the sinotubular junction. The space serves as a reservoir of blood during ventricular diastole. The *tubular portion of ascending aorta* is that portion beginning at the most cephalad extension of the sinuses of Valsalva and extending to the origin of the innominate artery (Fig. 1).

Methods

During an 18-month period, the measurements described herein were carried out in 100 hearts, which had been fixed in 10% buffered formalin. Death in all 100 patients was either the result of a noncardiac condition or to consequences of atherosclerotic coronary heart disease, a condition that does not affect the aortic valve. Patients with valvular, congenital, pericardial and primary myocardial diseases, patients in whom a cardiac operation had been performed, and patients younger than 18 years of age at death were excluded. If the heart was increased in mass the cause of the cardiomegaly was attributable only to systemic hypertension. Of the 100 patients, 2 were aged 18 to 20 years, 7 aged 21 to 30, 9 aged 31 to 40, 9 aged 41 to 50, 19 aged 51 to 60, 31 aged 61 to 70, 16 aged 71 to 80, 2 aged 81 to 90 and 5 aged 91 to 100 years. The heart weighed less than 400 g in 54 patients and more than 400 g in 46 patients. Of the 61 men, 28 (46%) had hearts less than 400 g and 33 (54%) had hearts more than 400 g; of the 39 women, 26 (67%) had hearts less than 400 g and 13 (33%) had hearts more than 400 g.

From the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Dr. Silver's present address: Section of Cardiology, Rush-Presbyterian-St. Luke's Medical Center, 1753 West Congress Parkway, Chicago, Illinois 60612. Manuscript received September 12, 1984, accepted October 8, 1984.

Address for reprints: William C. Roberts, MD, Building 10A, Room 3E30, National Institutes of Health, Bethesda, Maryland 20205.

One or more measurements were made in each patient on 6 structures or spaces. Of the 6, one measurement per patient was made in 2: heart weight and area of aortic lumen at the sinotubular junction. Of the other 4 structures or spaces, 3 measurements per patient were made because each patient had 3 aortic valve cusps and 3 sinuses of Valsalva. These 4 structures or spaces were: volume capacity of each sinus of Valsalva; weight of each aortic valve cusp; area of each aortic valve cusp; length of free margin of each cusp (measurement 1 [Fig. 2]); length of attachment margin of each cusp (measurement 2 [Fig. 2]); length from midportion of free margin to midportion of attachment margin (cuspal height) in each cusp (measurement 3 [Fig. 2]); and the straight-line distance between 2 junctions where free margins meet attachment margins of each cusp (cuspal width) (measurement 4 [Fig. 2]). Thus, in the 100 patients, 2,300 measurements of the 6 structures or spaces were possible; of these, 2,146 (93%) were carried out. The heart weight was determined in all 100 patients. The area of the aortic lumen at the level of the sinotubular junction was determined in 75 patients. The capacity of all 3 sinuses of Valsalva was determined in 68 patients or in 204 (68%) of the 300 sinuses. The weight of all 3 cusps individually was determined in 89 patients or in 267 of the 300 separate aortic valve cusps. The area of all 3 cusps was determined in all 100 patients or in all 300 of the possible 300 cusps. All 4 linear measurements (Fig. 2) were performed on each of the 3 aortic valve cusps in all 100 patients, yielding a total of 1,200 measurements of a possible 1,200 measurements.

The heart was weighed after cleaning all 4 cavities of postmortem clot and after excising both the ascending aorta and the pulmonary trunk about 2 cm above the cephalad extension of the semilunar valve cusps.

The volume capacity of each sinus of Valsalva was determined via a 2-ml pipette calibrated into 0.1-ml units. The pipette was filled to its capacity with water. While holding the heart with the sinuses of Valsalva roughly perpendicular to the long axis of the pipette, each sinus was filled to its capacity with water and the amount delivered by the pipette was recorded to the nearest 0.1 ml.

The luminal area of the aorta at the sinotubular junction was determined by incising circumferentially the aorta exteriorly while observing the blade of the knife within the aortic lumen. The thickness of the aortic wall circumferentially at the sinotubular junction was then blackened by a felt-tipped marking pen. The blackened aortic wall was then imprinted on white paper. Tracing paper was then superimposed over the black ring and the inner circumference was traced onto tracing paper. The cross-sectional area (in mm^2) of the aortic lumen then was determined directly by planimetry (KE-compensatory polar planimeter) using a video method described elsewhere.[1] The system was calibrated to 1-cm-square grid (100 mm^2). Each tracing then was placed under a focused camera and the resultant video signal was passed through an electronic integrator and displayed on a television monitor, which ensured that the area being measured was accurate. The analog output voltages of the video planimeters provided on-line measurements of the cross-sectional areas by a digital readout.

The aorta at the level of the aortic valve usually was opened between 2 cusps so that each cusp remained intact. Each of the 3 aortic valve cusps was excised intact along their curved line of attachment (just inside line 2 in Figure 2). Each cusp was then weighed using a Mettler P1210 scale, which has an accuracy to 0.01 g. Then each cusp was flattened (usually simply by applying water) on a sheet of white paper and the attachment margin (measurement 2 [Fig. 2]) and the free margin (measurement 1 [Fig. 2]) was traced onto the paper. The area enclosed by the tracing was measured by videoplanimetry as described above. Measurements 1 to 4 (Fig. 2) were made from the tracing by a flexible plastic metric ruler calibrated in 1-mm units.

Statistical methods: The comparison of means was done using an uncorrelated Student *t* test, and the correlation coefficients were calculated using a Pearson's product moment test. Significance was judged if the test yielded a p value <0.05.

Results

The findings are summarized in Tables I and II and in Figures 3 to 16.

The *sum of the areas of the 3 aortic valve cusps* increased with age (Fig. 3) ($r = 0.40$, $p < 0.001$), with heart weight (Fig. 4) ($r = 0.62$, $p < 0.001$); with total volume of the 3 sinuses of Valsalva (Fig. 5) ($r = 0.61$, $p < 0.001$); with the sum of the weight of the 3 aortic valve cusps (Fig. 6) ($r = 0.77$, $p < 0.001$), and with the aortic area at the sinotubular junction (Fig. 7) ($r = 0.75$, $p < 0.001$).

cuspal area, mean cuspal weight, mean sinus of Valsalva volume, and the means of the 4 cuspal linear measurements (numbers 1 to 4 [Fig. 2]) were highly ($p < 0.01$) significantly different for each cusp or sinus in patients with normal sized hearts (≤400 g) compared with the patients with hearts of increased mass (>400 g).

Smaller, insignificant differences occurred in mean sinus of Valsalva volume, and the means of the 4 cuspal

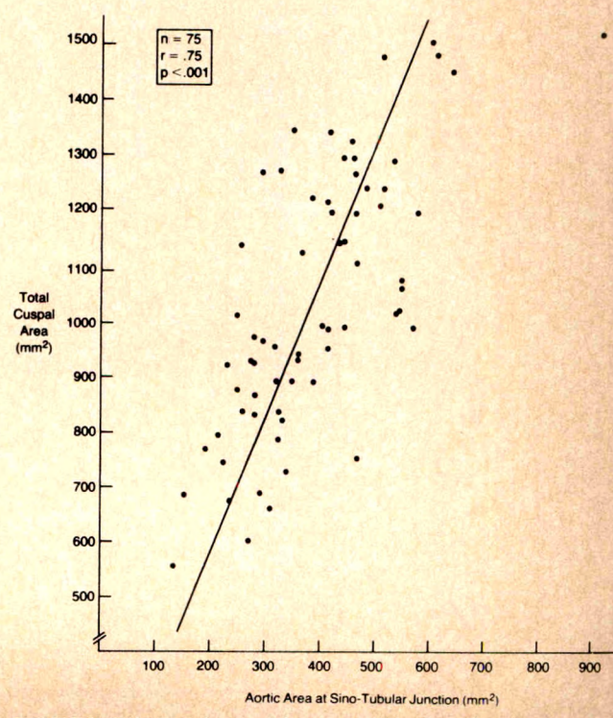

FIGURE 7. Relation of sum of the areas of the 3 aortic valve cusps to aortic area at the sinotubular junction.

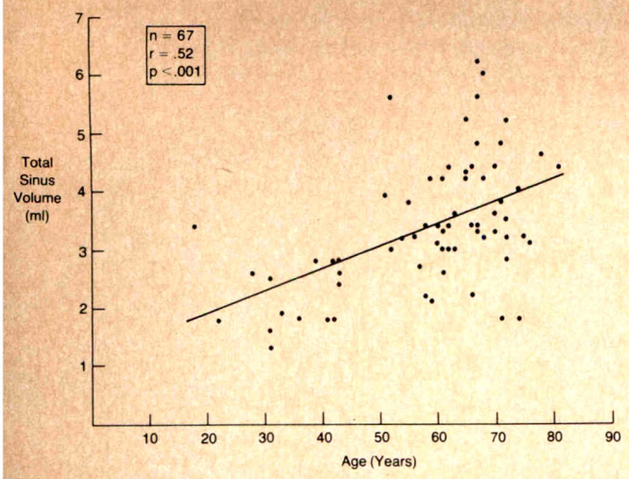

FIGURE 8. Relation of sum of volumes of the 3 sinuses of Valsalva to age.

linear measurements among the 3 cusps or sinuses between the 54 patients with normal-sized hearts (≤400 g) and those with hearts of increased mass (>400 g) (Table I). The posterior cusp, compared to both right and left ones, however, had a larger mean area and mean weight (Table I).

As summarized in Table II, only 16 patients had 3 equal-sized aortic valve cusps; 51 patients had 2 equal-sized cusps (1 different cusp), and 33 patients had no equal-sized cusps (all 3 cusps different). Among the 51 patients with 2 equal-sized cusps, the different-sized cusp was smaller than the other 2 in 25 patients and larger in 26 patients. The different-sized cusp was nearly equally split between the right, left and posterior locations. Of the 33 patients in whom none of the 3 cusps was of equal size, the posterior cusp was the largest in 20, the left in 7 and the right in 6; the posterior

hearts ≤400 g was 139 to 520 mm^2 (mean 333 ± 94); and in the 35 patients with hearts >400 g it was 256 to 915 mm^2 (mean 459 ± 124).

Discussion

The present observations provide detailed data on the area, weight and certain linear measurements on each of the aortic valve cusps and on the volumes of the sinuses of Valsalva in necropsied persons with normally functioning aortic valves. The sums of the aortic valve cuspal areas, cuspal weights and sinus of Valsalva volumes increased with age ($p < 0.001$) and with heart weight ($p < 0.001$). All 3 variables (cuspal area, cuspal weight and sinus of Valsalva volume) also increased with age and heart weight relative to each other. Additionally, the luminal area at the sinotubular junction also increased with age and heart weight, and it also increased as the sum of the aortic valve cuspal areas and weights and sinus of Valsalva volumes increased.

Detailed measurements of the aortic valve cusps disclosed that in only 16% of the patients were the 3 aortic valve cusps of similar sizes (<5% difference in area between cusps); in 51% of patients 1 cusp was of different size from the other 2, and in 33% of patients all 3 cusps were of different sizes. That aortic valve cusps are often of different size was pointed out by Roberts[2] in 1970, but actual measurements on each cusp were not performed. Vollebergh and Becker[3] in 1977 measured the "width," a measurement corresponding to our measurement 4 (Fig. 2), and "height," a mea-

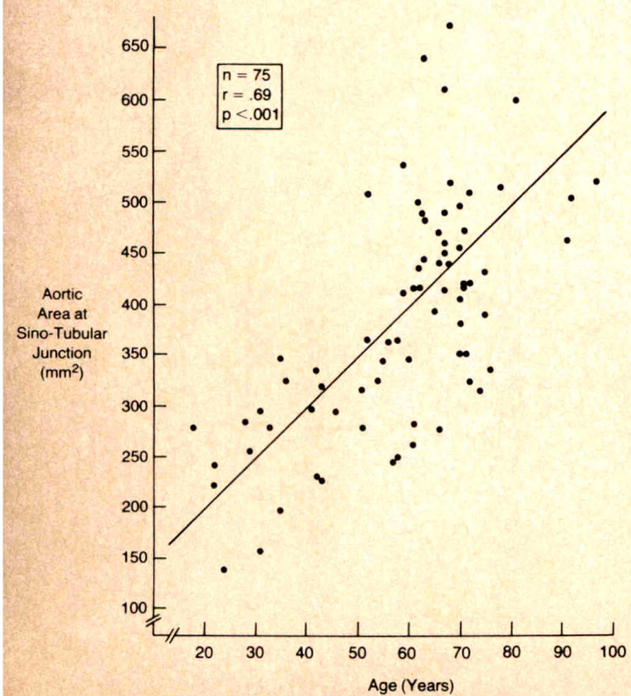

FIGURE 15. Relation of aortic area at sinotubular junction to age.

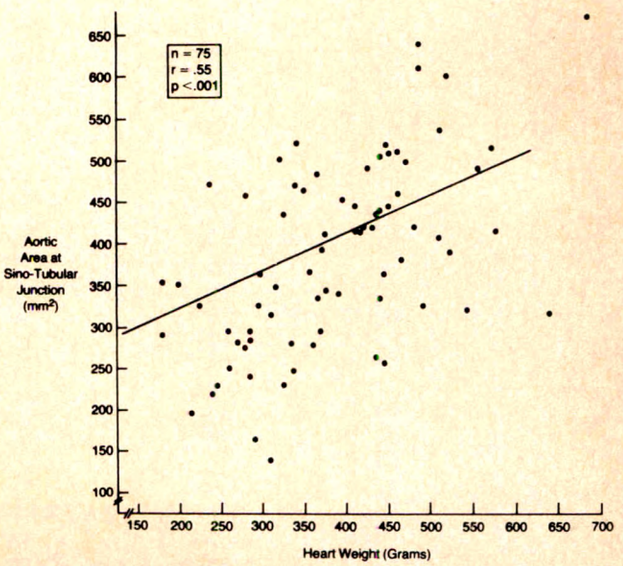

FIGURE 16. Relation of aortic area at sinotubular junction to heart weight.

surement corresponding to our measurement 3 (Fig. 2), in 200 necropsy patients ". . . who had no clinical signs of aortic stenosis and no other cardiac abnormality that could have affected the aortic valve." Both height and width of each cusp were usually different in each patient. The actual heights of the 3 cusps were not provided, however; the results of these measurements were expressed as a percentage of the width of the same cusp. The average width of the right cusp was 25.9 mm; that of the posterior cusp 25.5 mm and that of the left cusp 25.0 mm. Whether or not these differences are significant was not stated. These investigators also calculated the area of each cusp by applying the formula $\pi/4$ (width × height). Using this formula, they found that only 5 of the 200 hearts had cusps of equal areas and that 53 of the 54 hearts of patients younger than 40 years of age had cusps of unequal areas.

In contrast to the few studies describing measurements on the aortic valve in human beings,[3,4] several reports have described results of measurements on the ascending aorta. Krovetz[5] recalculated data gathered initially by Sutter[6] in 1897 and by Kani[7] in 1910 and demonstrated that the size of the aorta, at the level of the sinuses of Valsalva and 1 cm above the sinotubular junction and expressed as cross-sectional area per square meter of body surface area, decreases during the first 20 years of life and increases thereafter (r = 0.77). Several groups of investigators have described results of measuring the circumference of the aorta, presumably at the sinotubular junction, at necropsy. De La Cruz et al,[8] Rowlatt et al,[9] and Eckner et al[10] measured aortic circumference in children and found that it related to body surface area, weight and age. Hutchins and Anaya,[11] Davies[12] and Westaby et al[13] found wide variation in the circumference or diameter of the proximal aorta in adults and it was not importantly related to the size of the patient but it did increase with age.

Echophonocardiographic Estimates of Pulmonary Artery Wedge Pressure in Mitral Stenosis

PETER S. RAHKO, MD, JAMES A. SHAVER, MD, ROSEMARIE SALERNI, MD, WILLIAM H. GAMBLE, MD, and P.S. REDDY, MD

The efficacy of noninvasive indexes for predicting pulmonary artery wedge (PAW) pressure was reviewed in 77 patients with mitral stenosis. M-mode echocardiography and phonocardiography were used to measure the aortic valve closure–mitral valve E-point interval (A2-E) and the electrocardiographic Q wave–mitral valve closure interval (Q-C) close to the time of diagnostic cardiac catheterization. During catheterization, in 65 patients PAW pressure was measured and in 12 left atrial (LA) pressure was measured. The A2-E and Q-C intervals taken alone had only modest correlation with PAW pressure ($r = -0.54$ and $r = 0.46$, respectively). The correlation was weakest in patients with atrial fibrillation and best in sinus rhythm when heart rate variation between invasive and noninvasive studies was within ±5 beats. Substitution of V-wave pressure for mean PAW pressure and correction for variation in blood pressure improved the A2-E correlation ($r = -0.64$), as did combining the A2-E and Q-C intervals into a ratio [(Q-C)/(A2-E)] ($r = 0.62$). However, the best results were obtained in patients where LA pressure was measured directly ($r = -0.91$ for A2-E), suggesting the PAW pressure is not always an accurate reflection of LA pressure. In conclusion, many factors in addition to LA pressure affect the Q-C and A2-E intervals which, in many situations, decrease their predictive value. However, if used appropriately, these intervals may allow an estimation of PAW pressure.

(Am J Cardiol 1985;55:462–469)

Several echocardiographic[1–4] and phonocardiographic[5–8] indexes have been developed in an attempt to predict noninvasively pulmonary artery wedge (PAW) pressure. The oldest and most widely used method was originally derived in patients with mitral stenosis (MS), in whom both the interval from the electrocardiographic Q wave to mitral valve closure (Q-C) or first heart sound (Q-S1) and the interval from aortic valve closure to peak mitral valve opening (A2-E) or opening snap (A2-OS) are directly related to mean PAW pressure.[5–7] Other investigators later demonstrated that if these intervals were combined as a difference [(Q-C)-(A2-E)] or ratio (Q-C)/(A2-E), the strength of the relation improved.[8–10] These results have been extended from MS to all forms of cardiac disease, and studies using the (Q-C)/A2-E ratio have shown strong correlation with PAW pressure.[10–13] However, several variables in addition to PAW pressure affect the duration of both the Q-C and A2-E intervals, and in some situations, such as mitral regurgitation, the correlation of 1 of the intervals may be lost.[14] Thus, it is doubtful that 1 general equation can accurately predict PAW pressure in all situations. The present study evaluates the hemodynamic determinants of each of these intervals and the resultant ability of these intervals to accurately predict PAW pressure in a homogeneous population of patients with MS.

Methods

Records of patients with MS who were studied between June 1974 and October 1983 were reviewed. Patients with coexistent mitral regurgitation greater than 1+/4+ by left ventricular (LV) angiography, aortic regurgitation greater than 1+/4+ by aortic root angiography or aortic stenosis with mean pressure gradients greater than 20 mm Hg were excluded. The study group consisted of 77 patients (63 women and 14 men) aged 21 to 79 years (mean 49). Thirty-nine patients were in normal sinus rhythm, 37 in atrial fibrillation and 1 in atrial flutter.

Invasive data: All patients underwent diagnostic right- and left-sided cardiac catheterization and angiography in the fasting state. In 65 patients, the mitral gradient was determined by simultaneous recordings of LV and PAW pressures obtained with either a No. 7Fr Lehman or Swan-Ganz cath-

eter, which was adequately flushed to prevent damping and in stable position confirmed by fluoroscopy. In 12 patients, direct left atrial (LA) pressures were recorded using a Ross transseptal catheter. All recordings were obtained on a multichannel physiologic recorder.

Peak LV systolic, mean PAW or LA, PAW or LA V-wave and LV end-diastolic pressures were determined by averaging the pressures of a complete respiratory cycle. In patients who had simultaneous LA and LV pressures recorded, the pressure at LA–LV crossover in early systole was also obtained (Fig. 1).

Noninvasive data: All patients underwent both M-mode echocardiography and phonocardiography and 67 patients were examined within 4 days of catheterization. Ten patie were studied within 5 to 20 days of catheterization, and significant clinical change was manifested during the inter period.

Patients were studied with simultaneous recordings of t phonocardiogram, mitral valve echocardiogram and electr cardiogram except for 6 patients who had separate recordir of the phonocardiogram and echocardiogram during the sa study. Heart rates were within 2 beats for these 6 patients. recordings were made on a multichannel photographic corder and 66 studies were recorded at a paper speed of 1 mm/s with 20-msec time lines, allowing interval measu ments to within ±4 ms.[15] The 11 remaining studies were

(Q-C)/(A2-E) vs mean PAW or LA	0.62	0.60	0.87
[(Q-C)-(A2-E)] vs mean PAW or LA	0.63	0.62	0.85

* $p < 0.038$; in all other cases, $p < 0.00025$. Intervals are as defined in the text.
LA = left atrial pressure; LA-LV crossover = pressure at the early systolic crossover of left ventricular and LA pressure, LV end-diastolic = left ventricular end-diastolic pressure; PAW = pulmonary artery wedge pressure; V-wave = peak of the V-wave pressure; V/LV = peak of the V-wave pressure divided by peak LV pressure.

corded at 50 mm/s with 20-ms time lines. Phonocardiograms were obtained from the second left intercostal space and the cardiac apex using standard microphones. All patients were examined in the supine or in the left lateral position and the mitral valve echocardiogram was obtained using standard techniques. In patients with atrial fibrillation, complexes with R-R intervals as closely as possible approximating the R-R intervals used in recording the pressures at catheterization were chosen.

The following intervals were measured from 5 cardiac cycles and averaged (Fig. 2):

(1) A2-E, A2-OS: The intervals from the first high-frequency vibration of the aortic component of the second heart sound (A2) to the next 2 points: (a) the maximal early diastolic excursion point (E) of the anterior mitral leaflet or (b) the first high frequency vibration of the opening snap (OS).

(2) Q-C, Q-S1: The intervals from the onset of the QRS complex of the electrocardiogram (Q) to either (a) the point of termination of the last posterior motion of the mitral valve anterior leaflet (C)[16] or (b) the first high-frequency component of the first heart sound (S1).

The hemodynamic and noninvasive measurements were made independently. The noninvasive intervals were compared to the invasive measurements of PAW, LA or LA-LV crossover pressure by linear regression analysis.

Results

All study patients had MS, with LA-LV or PAW-LV mean diastolic pressure gradients averaging 13 mm Hg (range 2 to 32). Almost all patients had normal LV function. The average LV end-diastolic pressure was 9 mm Hg (range 1 to 20; greater than 14 mm Hg in only 3 patients) and the average ejection fraction was 58% (range 46 to 82). Peak LV pressure averaged 123 mm Hg (range 90 to 175).

Heart rate averaged 77 beats/min (range 53 to 123). Since the invasive and noninvasive studies were not simultaneous, there was heart rate variation between studies. The correlation, by linear regression, between heart rates in the invasive and noninvasive studies was $r = 0.71$ ($p < 0.00001$). To determine whether or not heart rate variation may have adversely affected the results for the group as a whole, progressively tighter restrictions were placed on the allowable heart rate range with each of the correlations reported in the study. There was no improvement in any correlation as the allowed heart rate variation was decreased. However, the groups formed by applying the heart rate re-

TABLE II Effect on Heart Rate Variation Between Noninvasive and Invasive Studies in Patients in Sinus Rhythm and a Comparison of Correlations Between A2-E and Q-C in Sinus Rhythm and Atrial Fibrillation

	All Patients (n = 77)	Atrial Fibrillation (n = 38)	Sinus Rhythm (n = 39)	Sinus Rhythm + 5 (n = 14)
A2-E vs mean PAW or LA	−0.54	−0.42	−0.63	−0.78
A2-E vs V-wave	−0.55	−0.39	−0.68	−0.83
A2-E vs V/LV	−0.64	−0.52	−0.72	−0.78
Q-C vs mean PAW or LA	0.46	0.44	0.47	0.67
(Q-C)/(A2-E) vs mean PAW or LA	0.62	0.60	0.64	0.83
[(Q-C)-(A2-E)] vs mean PAW or LA	0.63	0.58	0.67	0.84

$p < 0.0008$ for all correlations.
Sinus rhythm ±5 = No greater than a 5-beat variation in heart rate between the invasive and noninvasive studies. All other abbreviations as in Table I.

striction were comprised mainly of patients who were in atrial fibrillation. Thus, the results are analyzed first for the group as a whole and then repeated after division into groups containing only atrial fibrillation and only sinus rhythm.

Both the A2-E and A2-OS intervals were measured. The opening snap was absent in 26% of subjects, but in the remainder the A2-OS interval correlated almost exactly with A2-E (r = 0.99) (Fig. 3A). The Q-S1 and Q-C intervals could be measured in all patients and correlated very well with each other (r = 0.98) (Fig. 3B). In this study, the Q-C and A2-E intervals were used for all pressure correlations.

The average mean PAW pressure was 18 mm Hg (range 5 to 45) and the average V wave of the PAW or LA pressure was 22 mm Hg (range 6 to 52). The mean and V-wave pressures correlated closely with each other (r = 0.84).

There was a significant negative correlation of the A2-E interval with both mean PAW and LA pressures and also with the V wave of PAW and LA pressure. (Table I.) The correlation was much stronger for LA than for PAW pressure. Dividing the V-wave pressure by peak LV pressure to correct for systemic blood pressure variation further strengthened the correlations (Table I).

The Q-C interval significantly correlated with mean PAW and LA pressures, but the correlation was not as great as with the A2-E interval (Table I). With this interval, restricting the analysis to only the LA pressure group resulted in only minor improvement in the correlation. In the LA pressure group, correlation was also made with LA-LV crossover pressure and Q-C, but only minor improvement was noted. A further attempt to correct for variations in LV end-diastolic pressure by comparing Q-C to [(LA-LV crossover pressure) − (LV end-diastolic pressure)] also resulted in minor further improvement in the correlation (Table I).

The combination of the Q-C and A2-E intervals into either a ratio (Q-C/A2-E) or difference [(Q-C)-(A2-E)] was correlated with mean PAW and LA pressures. For the group as a whole and for the PAW pressure group, there was, compared with either interval alone, an improvement in the strength of the correlations (Table I). However, in the LA group, the strength of the correlation decreased compared with the correlation with A2-E alone (Table I).

The above relations were then reanalyzed separately for those with atrial fibrillation and those with sinus rhythm. The correlations were weaker in those with atrial fibrillation and stronger in those with normal sinus rhythm, particularly with the A2-E interval. In the sinus rhythm group, if the heart rate variation between invasive and noninvasive studies was restricted to ±5 beats, all correlations improved further (Table II).

Discussion

Several echocardiographic,[1–4] phonocardiographic[5–9,17–19] and combined echophonocardiographic[10–14] indexes have been developed to noninvasively predict PAW pressure. The most successful has been the ratio

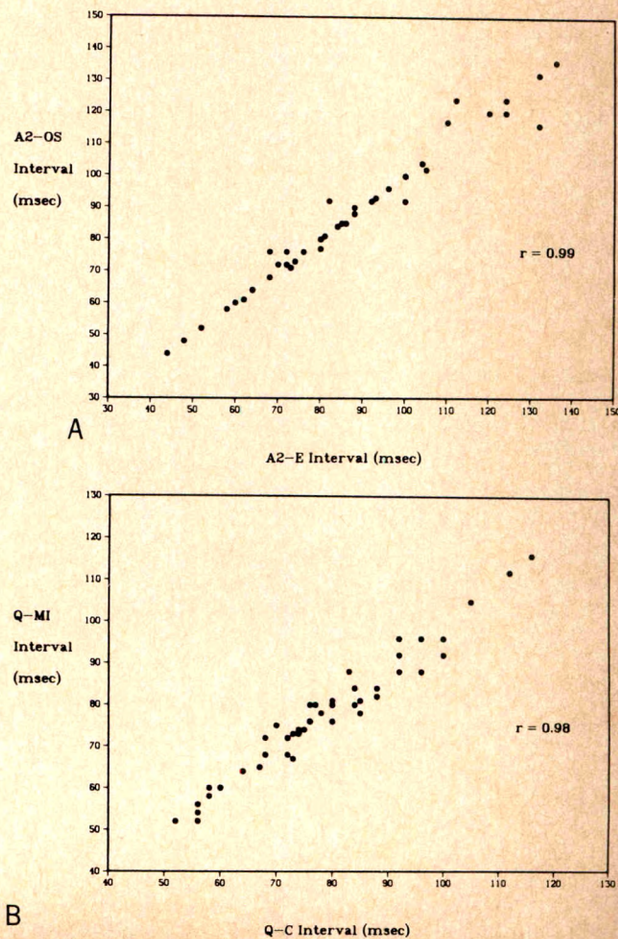

FIGURE 3. A, relation between A2-E interval and the A2-OS interval. **B,** relation between the Q-C interval and the Q-M1 interval.

of (Q-C)/(A2-E) for which several predictive regression equations have been published.[9–13]

The A2-E interval defines a period of time in early diastole during which pressure in the LV rapidly falls from the time of aortic valve closure to the point of maximal anterior deflection of the mitral valve leaflets (Fig. 4). The fundamental assumption which makes this interval useful is that as LA pressure rises, the time from A2 to pressure crossover shortens and hence the A2-E interval shortens.

However, several other variables besides LA pressure help determine the A2-E interval, thus decreasing the consistency of the relation between patients with different types of cardiac disease. LV pressure at the time of A2 may vary considerably. Thus, for a given LA pressure, a hypertensive patient will have a larger pressure drop and, hence, a longer A2-E interval than a hypotensive patient. Since LV pressure at the time of A2 is difficult to measure, peak LV pressure has been used instead and V/LV or the difference LV-V has been used to correct for variation in LV pressure at the time of aortic closure. As demonstrated in this study and previously,[8,9] this generally results in an improved correlation with A2-E (Fig. 5).

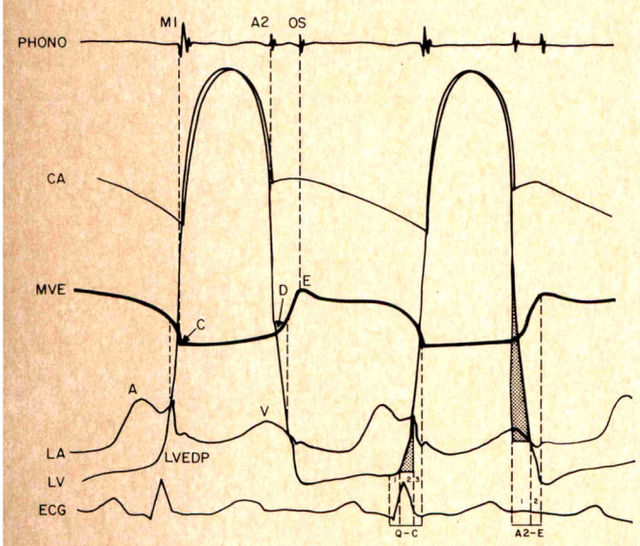

FIGURE 4. Simultaneous micromanometer-derived left ventricular (LV), left atrial (LA) and central aortic pressures with an electrocardiogram, phonocardiogram and mitral valve echocardiogram (MVE) to illustrate the interrelationships between sound, mitral valve motion and hemodynamic events that affect the A2-E and Q-C intervals. The **left** complex shows that pressure crossover occurs before mitral valve closure and the C point, or closure point, of the mitral valve is coincident with the mitral component (M1) of the first heart sound. LV pressure at the time of A2 is demonstrated and the mitral valve E point and opening snap are coincident. Mitral valve opening (D point) begins before pressure crossover. In the **right** complex, the determinants of the 2 intervals are shown. The Q-C interval may be divided into 3 sections. Section 1 represents electromechanical coupling of the left ventricle from the Q wave to the onset of pressure increase. Section 2 represents the time needed to overcome the difference between LA pressure and LV end-diastolic pressure (LVEDP) and will prolong as the pressure gap between the 2 chambers widens. Section 3 represents the interval from pressure crossover to actual mitral valve closure and is a function of mitral valve compliance and momentum of the forward-flowing blood column. The A2-E interval may be divided into 2 sections. Section 1 represents the time from A2 to pressure crossover and will be affected by the rate of LV pressure decrease (−dP/dt), the LV pressure at the time of A2 and LA pressure at the time of pressure crossover. Section 2 is a function of the compliance of the mitral valve. A = A wave of left atrial pressure; CA = central aortic pressure, D = onset of opening of the mitral valve; phono = phonocardiogram; other abbreviations as defined in Figures 1 and 2.

By relating A2-E to the V-wave pressure instead of mean LA or PAW pressure, there should theoretically be an improvement in correlation, since the V wave occurs during the A2-E interval and determines the point where the mitral valve begins to open (Fig. 4). The importance of using the V wave becomes proportionately greater as the degree of mitral regurgitation increases. When significant regurgitation is present, the A2-E interval taken alone correlates more strongly with PAW pressure than the ratio Q-C/A2-E.[10] In the present study, significant mitral regurgitation was purposely excluded and, thus, there was only a slight improvement in the A2-E relation when V-wave pressure was substituted for mean LA or PAW pressure. (Table I).

The mobility of the mitral valve probably plays only a minor role in the A2-E interval. Mitral valve motion is initiated slightly before LA-LV pressure crossover and the E point clearly occurs after crossover[20,21] (Fig. 4). However, the exact timing of the E point relative to pressure crossover is variable and is not directly related to either the severity of MS or the height of LA pressure.[20,21]

The rate at which LV pressure decreases because of relaxation is the other major independent factor affecting the A2-E interval. Since relaxation rate may vary, depending on the presence of certain primary myocardial diseases, the consistency of the A2-E relation between patients with different myocardial disease states but the same PAW pressure will be decreased. In this study, variation in relaxation rate, except that related to differences in peak LV pressure,[22] should have been minimal since LV function was essentially normal in all.

The Q-C interval is a measure of the initial events of systole and multiple factors affect its length.[14] In patients with MS, if all other variables are held constant, the interval should lengthen as LA pressure increases due to an increasing pressure difference between LV end-diastolic pressure and LA pressure (Fig. 4). This study has shown the Q-C correlation with mean LA or PAW pressure to be weaker than the corresponding A2-E correlation. Even when LA-LV crossover pressure is precisely defined, there is little further improvement in correlation (Table I).

In MS, the relation of mitral valve closure to LA-LV pressure crossover is analogous to the relation previously discussed with opening in that the C point does not occur until after pressure crossover[20,21] (Fig. 4). Again, there is a range of variation in the LA-LV pressure crossover to C-point interval, but there is no clear relation to LA pressure, mitral mobility or other factors.[20,21] When significant mitral regurgitation is present, the correlation between Q-C and mean PAW or LA pressure disappears.[14] This may reflect the fact that the large V-wave pressure, which has no physiologic relationship to Q-C, is the primary determinant of LA

or PAW pressure when mitral regurgitation is present.

Several studies using the (Q-C)/(A2-E) ratio in patients with normal mitral valves have demonstrated significant relationships between the Q-C interval and either PAW or LV end-diastolic pressure.[10–13] Because in these patients a pressure difference between LV end-diastolic and LA pressure is no longer present, the Q-C interval does not represent the time delay for LV pressure to exceed LA pressure. Instead, it probably represents a progressive decrease in positive dP/dt that occurs when LV dysfunction is present.[23] Other factors that affect the Q-C interval include the length of the PR interval and the presence of conduction system disease affecting the left ventricle.[24]

Since the Q-C and A2-E intervals change in opposite directions as LA pressure increases, the combination of these intervals into a difference [(Q-C)-(A2-E)] or ratio (Q-C)/(A2-E) has been used to accentuate the effect of pressure changes and minimize the effect of the other variables.[8–13] Our study agrees with others in that the combinations of the 2 intervals have a stronger correlation with PAW pressure than either interval taken alone (Fig. 6). However, in the subgroup of patients who underwent transseptal catheterization, there was marked improvement in the A2-E interval correlations but little improvement in the Q-C relation. Thus, when the 2 intervals are combined, the correlation with mean LA pressure decreases, probably because the weaker Q-C relation detracts from the stronger A2-E relation. It is generally assumed that mean PAW pressure is an accurate reflection of mean LA pressure; thus, it is somewhat surprising in this study that there was also a marked improvement in mean LA pressure correlation with A2-E compared with mean PAW pressure. The reason for enhanced correlation with LA as opposed to PAW pressure is probably the effects of damping, which occur to some degree in all PAW pressure tracings. This

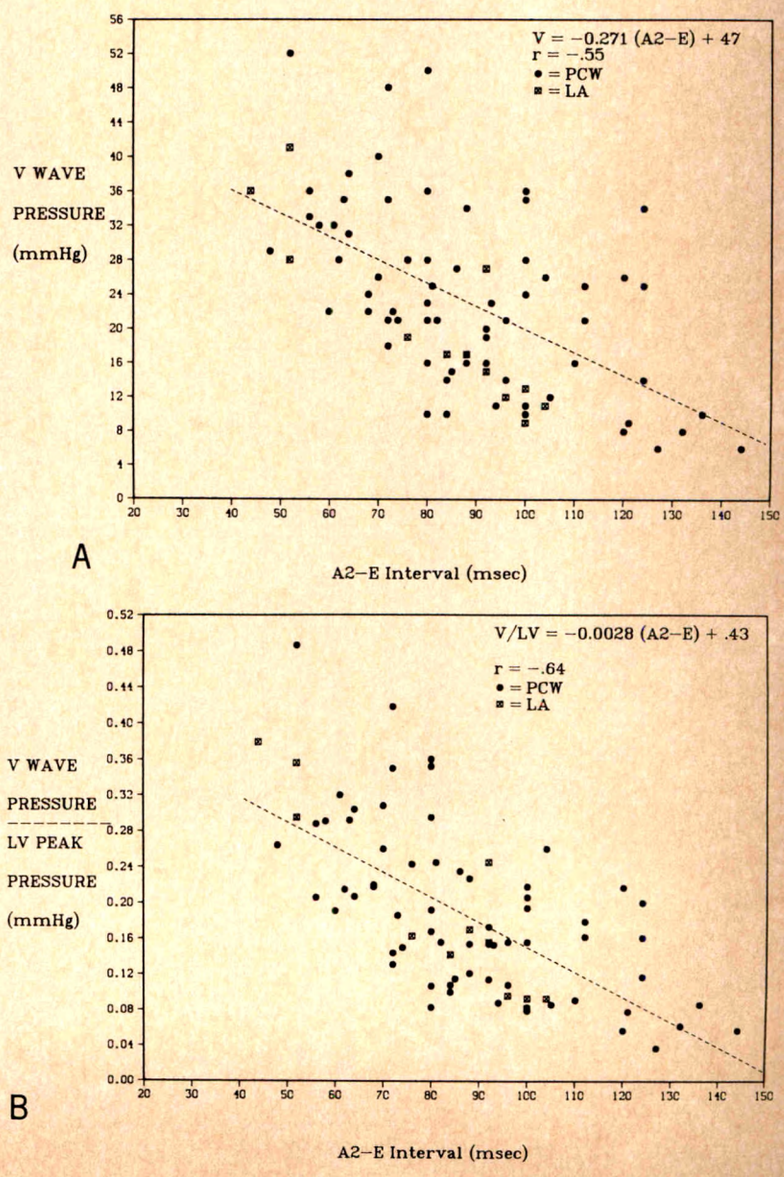

FIGURE 5. A, relation between the A2-E interval and V-wave pressure of both the pulmonary artery wedge (PAW) and left atrial (LA) pressures. **B,** relation between the A2-E interval and (V-wave pressure)/(peak left ventricular pressure) illustrating the improvement in correlation noted when correction is made for variation in peak left ventricular pressure.

TABLE III Comparison of Predicted Pulmonary Artery Wedge Pressure from Five Linear Regression Equations When a Spectrum of Values for (Q-C)/(A2-E) Is Substituted

Study	Regression Equation	r Value	Predicted PAW Pressure When the Ratio of (Q-C)/(A2-E) is: 0.25	0.5	0.75	1.0	1.5	2.0
Yigitbasi et al[9]*	17.8x + 1.33	0.91	6	10	15	19	28	37
Palomo et al[10]†	21.6x + 1.1	0.93	6	12	17	23	33	44
Abdulla et al[11]‡	18.8x + 1	0.87	6	11	16	21	30	39
Askenazi et al[13]§	34.2x − 2.1	0.91	6	15	24	32	49	66
Present study	12.8x + 6.0	0.62	9	12	16	19	25	32

* Phonocardiographic study in mitral stenosis using (Q-S1)/(A2-OS); † used (Q-C)/(A2-E) vs left ventricular end-diastolic pressure, but also used to predict pulmonary artery wedge pressure with and without mitral stenosis; ‡ used (Q-C)/(A2-E) vs pulmonary artery wedge pressure in patients without mitral stenosis; § did not use phonocardiogram but used echocardiogram of aortic valve to determine time of A2 in patients without mitral stenosis.

x = (Q-C)/(A2-E) or equivalent.

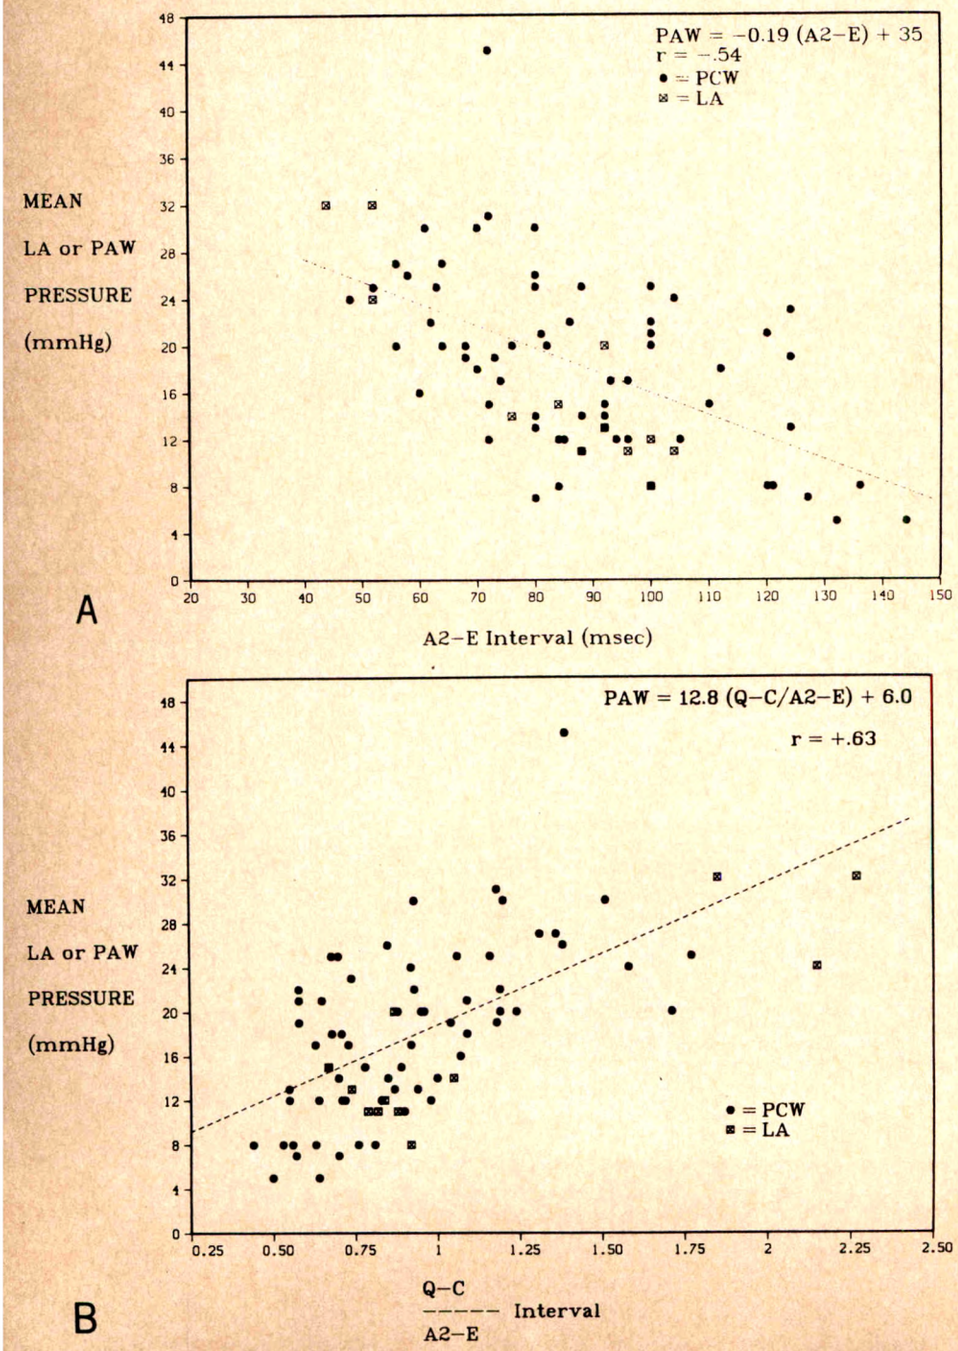

FIGURE 6. A, relation between the A2-E interval and mean pulmonary artery wedge (PAW) and left atrial (LA) pressures. **B,** relation between the ratio of (Q-C)/(A2-E) and mean PAW and LA pressure.

is most likely because of (1) the softer and smaller-lumen catheters used in right-sided cardiac catheterization, particularly balloon-tipped catheters; (2) changes in PAW pressure produced by local variations in pulmonary artery vasculature; (3) variable loss of amplitude of LA pressure variations across the pulmonary capillary bed especially at lower LA pressures; (4) the effects of primary pulmonary disease states; and (5) misinterpretation of a damped pulmonary artery pressure as PAW pressures.[25,26]

Several regression equations to predict PAW pressure have been developed and are listed in Table III, along with the PAW pressure estimates which would be obtained if representative values for the (Q-C)/(A2-E) ratio were substituted to represent a typical spectrum of ratios. Although there is reasonable agreement at low pressures, there is a marked divergence in predicted PAW pressure at high pressures. The variations in these results reflect to some degree minor differences in methodology of data acquisition and measurement. More important, these equations represent the patient population used to generate them and show that it is doubtful, no matter how strong the correlation in a given study is, that 1 regression equation can successfully predict PAW pressure in all patients, because several factors in addition to PAW pressure affect these intervals.

The Q-C and A2-E intervals may be useful for predicting PAW pressure in certain situations if the above limitations are recognized. For example, if a predictive equation is developed in a homogeneous population, that equation should give a reasonable quantitative estimate of PAW pressure in patients with a similar disease. Also, although in most situations the Q-C/A2-E ratio is the best estimation of PAW pressure, in some settings, particularly when significant mitral regurgitation is present or a left-sided conduction delay is noted, the A2-E interval alone is more reliable.

Acknowledgment: We express our appreciation to Alfred Cecchetti for assistance in preparing the statistics and illustrations, to Darlene Yourick for typing the manuscript and to Albert Durica for his assistance with illustrations.

Medically Directed At-Home Rehabilitation Soon After Clinically Uncomplicated Acute Myocardial Infarction: A New Model for Patient Care*

The University of Alabama School of Medicine designates this continuing medical education activity for 1 credit hour in Category 1 of the Physician's Recognition Award of the American Medical Association. Answers are to be marked on the instruction sheet on page 504.

1. In this study, 5 patients were excluded after randomization because of complications after:
   a) elevation of serum creatine kinase
   b) elevation of oxaloacetic transaminase
   c) treadmill exercise testing
   d) new Q waves appeared

2. The mean age of 198 training study participants was:
   a) 64 years
   b) 31 years
   c) 37 years
   d) 52 years

3. Eighty-six percent of the subjects were employed with professional and managerial roles constituting:
   a) 24%
   b) 15%
   c) 56%
   d) 31%

4. Treadmill exercise testing was terminated if the patient experienced:
   a) chest pain, dyspnea, fatigue or leg cramps
   b) hypotension
   c) ventricular tachycardia
   d) any of the above

5. Patients assigned to home training who were free of treadmill angina at 3 weeks were:
   a) in the vast majority
   b) in the minority
   c) instructed to walk briskly
   d) loaned a stationary bike for exercise

6. The program nurse was able to obtain electrocardiographic data on the exercising patient at home by:
   a) telephone and transmission of M-CL5 bipolar lead electrocardiogram
   b) having the patient come in twice weekly
   c) having the patient come in once weekly
   d) having the patient phone in his readings daily

7. Telephone calls permitted verification and detection of changes in:
   a) training intensity
   b) patients clinical status
   c) medication use
   d) all of the above

8. Treadmill-induced ventricular tachycardia in patients who demonstrated treadmill-induced ventricular bigeminy at 3 weeks was absent in:
   a) 52%
   b) 32%
   c) 28%
   d) 14%

9. The number of patients withdrawn from this study solely because of exercise-induced ischemic ST-segment depression was:
   a) 0
   b) 20
   c) 14
   d) 5

10. Of the 600,000 Americans surviving acute myocardial infarction each year, this study suggests that the approximate number capable of safely completing 3 months of at-home rehabilitation is:
    a) 75,000
    b) 300,000
    c) 100,000
    d) none of the above

Transderm®-Nitro

(nitroglycerin)
Transdermal Therapeutic System

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)*

INDICATIONS AND USAGE
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response. The Transderm-Nitro 2.5 system is useful princi pally for decreasing the dosage gradually, though it may provide adequate therapy for some patients when used alone.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

HOW SUPPLIED

Transderm-Nitro System Rated Release *in vivo*	Total Nitro-glycerin in System	System Size	Carton Size
2.5 mg/24 hr	12.5 mg	5 cm^2	30 Systems (NDC 0083-2025-26)
5 mg/24 hr	25 mg	10 cm^2	30 Systems (NDC 0083-2105-26)

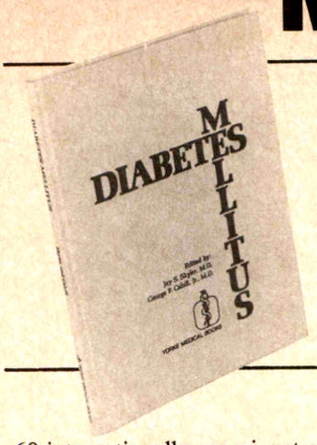
DIABETES MELLITUS



From the publishers of the American Journal of Medicine

Jay S. Skyler, M.D.,
University of Miami School of Medicine

George F. Cahill, Jr., M.D.,
Harvard Medical School and Howard Hughes Medical Institute

60 internationally prominent contributors provide in 26 papers a comprehensive overview of the current thinking on the causes, mechanisms, treatment and complications of diabetes.

Featured topics include:

- ☐ The causes of diabetic inheritance
- ☐ Immune factors of diabetes
- ☐ Mechanisms of diabetes (The culmination of 50 years of research)
- ☐ Autoimmunity
- ☐ New understandings in the mechanisms of insulin dependent and non-dependent diabetes mellitus
- ☐ New developments in the treatment of diabetes
- ☐ Methods of monitoring blood glucose and the use of glycosylated hemoglobin
- ☐ Pharmacology of oral hypoglycemics
- ☐ Use of insulin infusion devices
- ☐ Human insulin produced by recombinant DNA technology

If it is important to you in your practice to stay up-to-date on the latest developments in Diabetes Mellitus and you need a quick reference on the topic, then this is the book for you.

New Insights

The Complete Cardiac Lab.

How do you measure commitment? With words? Toshiba prefers to have the products make the point. Newest proof: the Toshiba SSH-40A Cardiac Ultrasound Laboratory, a vivid example of our commitment to echocardiographic diagnostics.

Clinical versatility is the watchword for the SSH-40A. It means independent or simultaneous display of 2-D echocardiograms, M-Mode and Doppler images for faster, more complete diagnosis. It means you can scan with various probes for the best image quality in all patient sizes and specialized procedures. Perform two dimensional, multigate array Doppler flow studies and perform all cardiac function computations instantly.

tain the most significant diagnostic information. The SSH-40A captures and displays them with a unique, low-noise digital system: dual microprocessors and more memory than any ultrasound instrument. Plus the powerful Digital Scan Processor provides optimum control over image quality.

Such insights, frankly, defy words. That's why we're eager to provide you with a demonstration of the SSH-40A's powerful capabilities. Then you can complete the picture yourself.

Please see the reverse side for further information.

New Insights

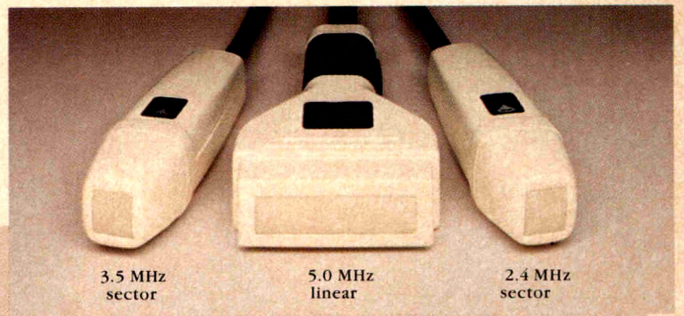
TOSHIBA SSH-40A CARDIAC ULTRASOUND LABORATORY.

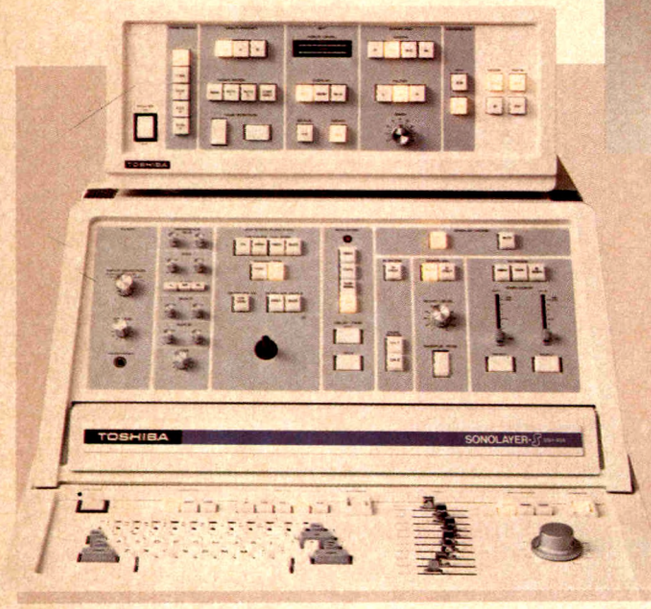
The Toshiba SSH-40A is a complete cardiac ultrasound laboratory that combines clinical versatility, superior image quality and powerful digital scan processing to provide a host of features for new insights into cardiac diagnoses.

The SSH-40A is available with a standard 3.5 MHz probe and optional 5 MHz linear scan probe and 2.4 MHz sector scan probe to enable accurate examinations of all patients, from neonates to adults. All pertinent image and exam data, including results from computations, can be displayed. And the unique two dimensional multigate array Doppler capability enables the operator to perform flow studies, to display frequency spectrum from the digital FFT analyzer and to compute flow rate, velocity and other cardiac function data. Extensive computational algorithms are on-line to ensure fast, accurate analyses.

Superb image quality results from the advanced scanning technology incorporated in the SSH-40A. A new receiver design and a new digital scan processor provide optimized image quality with clearly defined edge differentiation and excellent tissue differentiations. A faithful display of low level echoes provides excellent gray scale resolution.

The SSH-40A delivers the image processing functions cardiologists require. Echo enhancement, post processing and other echo processing operations, synchronous freezing of two phases of a cardiac cycle, slow motion display and measurement of distances and areas on frozen images are all well within the range of this remarkable system's capabilities.





- Simultaneous 2-D imaging and dual M-Mode or Doppler operation ensures more exact correlation, faster diagnosis and state-of-the-art performance.
- Cardiac function (SV, EF, FS, CO and others), area, circumference, slope and distance can be computed at the touch of a keyboard, thanks to a selection of stored algorithms.
- Simultaneous display of two images, strobed from two selected points on the ECG cycle, allows detection of abnormal wall motion.
- Comprehensive exam data display permits date, time, frequency and patient data and image annotation to be included for more complete patient records.

For further information on the SSH-40A electronic sector scanner, or other Toshiba Medical Systems' products, please call toll free 800-421-1968, in California call (714) 730-5000 or write Toshiba Medical Systems, 2441 Michelle Drive, Tustin, CA 92680.

Drug Treatment of Heart Failure

edited by Jay N. Cohn, MD

0-914316-41-9, approx. 250pp., Oct. '83, $35.00

This volume is aimed at providing clinicians with the physiologic and pharmacologic background necessary to effectively and efficiently create and administer drug therapy regimens for their patients who suffer heart failure. All efforts were made to ensure that the timeliness of each chapter, prepared by internationally respected clinicians and medical scientists, would not be compromised by delays in publication. Consequently, this book presents the very latest thinking on the utilization of drug therapy for heart failure and contains many references as recent as 1982 and 1983. This book is highly recommended to all physicians presently treating patients with heart failure.

TABLE OF CONTENTS AND CONTRIBUTORS

Foreword by Jay N. Cohn, MD

Chapter I
The Treatment of Heart Failure in Perspective: An Overview
by Jay N. Cohn, MD

Chapter II
Pathophysiology of Heart Failure: Deficiency in Cardiac Contraction
by John E. Strobeck, MD, and Edmund H. Sonnenblick, MD

Chapter III
The Role of the Renin—Angiotensin—Aldosterone System in the Pathophysiology of Chronic Heart Failure
by Robert J. Cody, MD, and John H. Laragh, MD

Chapter IV
Pathophysiology of Congestive Heart Failure: The Role of The Kidney
by Norman K. Hollenburg, MD

Chapter V
Congestive Heart Failure: Diagnosis and Principles of Treatment
by Elliot Rapaport, MD

Chapter VI
Conventional Drug Therapy in the Management of Heart Failure
by James E. Doherty, MD

Chapter VII
The Role of Inotropic Agents in the Management of Heart Failure
by Gary S. Francis, MD

Chapter VIII
Vasodilator Therapy of Heart Failure
by Kanu Chatterjee, MB, FRCD

Chapter IX
Captopril in Heart Failure
by William W. Parmley, MD

Chapter X
A Comprehensive Approach to the Treatment of Heart Failure
by Jay N. Cohn, MD

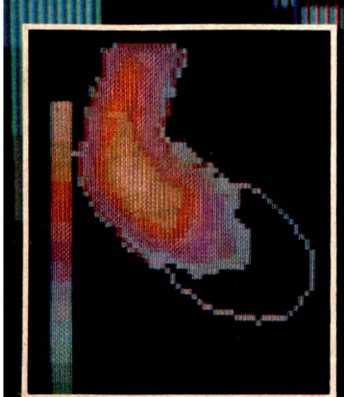
In choosing a diuretic for the treatment of edema due to congestive heart failure

Unsurpassed loop diuretic efficacy



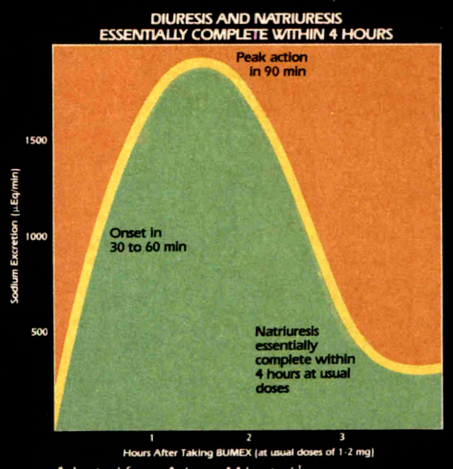
First-pass Radionuclide Angiocardiography displaying a markedly reduced left ventricular ejection fraction in a patient with congestive heart failure. The comparison view (inset at left) shows normal contraction in a patient without heart disease.

right © 1985 by Hoffmann-La Roche Inc. All rights reserved.

iuresis essentially complete within hours with Bumex at usual doses[1,2]

aster completion of diuresis with unsurpassed ficacy: that's what makes Bumex easy to live ith compared to other loop diuretics.

Bumex rapidly mobilizes a high volume of uid and sodium in edematous patients with ongestive heart failure.[3] And Bumex is unsur-assed in reducing edema and improving the nctional status of CHF patients.[4,5]

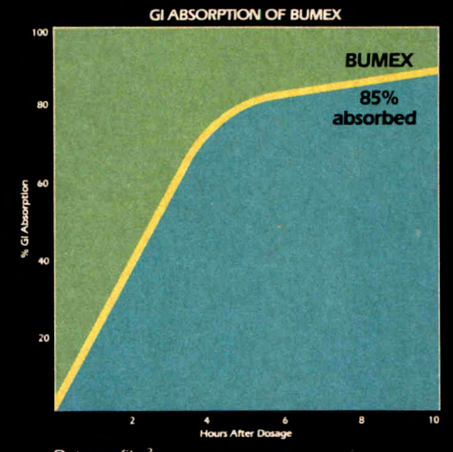


Adapted from Asbury MJ, *et al.*[1]

ffective diuresis through rapid, early complete absorption

ghty-five percent of an oral dose of Bumex absorbed through the GI tract;[3] thus the uretic response you can expect with oral umex is almost equal in magnitude to the sponse you get with an I.V. dose.[3,6]

As with all loop diuretics, excessive doses Bumex can lead to profound diuresis with ater and electrolyte depletion, including ypokalemia. Serum electrolytes should be onitored periodically, especially in patients n low-salt diets or those treated for pro-nged periods or on high doses.



Data on file.[3]

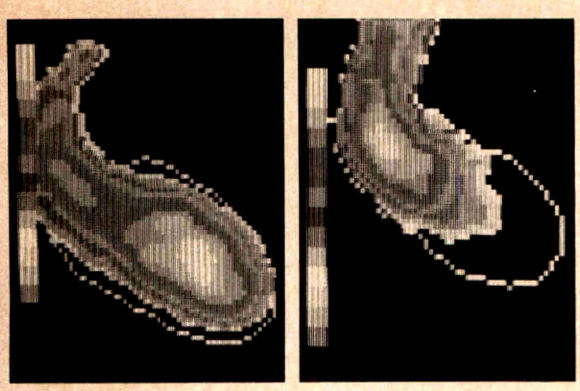
Bumex®

bumetanide/Roche

0.5-mg and 1-mg scored tablets/2-ml ampuls, 2-ml, 4-ml and 10-ml vials (0.25 mg/ml)

Faster completion of diuresis that's easier to live with

Faster completion of diuresis... that's easier to live with.



First-pass Radionuclide Angiocardiography displaying a markedly reduced left ventricular ejection fraction in a patient with congestive heart failure. The comparison view (on right) shows normal contraction in a patient without heart disease.

- Essentially completes diuresis within 4 hours, at usual doses
- Among loop diuretics, unsurpassed in volume of fluid and sodium excreted
- Unsurpassed in reducing edema and improving functional status
- Rapidly, nearly completely absorbed—for a predictable diuretic response
- Allows for early-evening diuresis—for days of normal activity, nights of uninterrupted sleep
- Contraindicated in anuria, markedly elevated BUN, hepatic coma and severe electrolyte deficiency
- The most frequent clinical adverse reactions considered probably or possibly related to Bumex are: muscle cramps, dizziness, hypotension, headache, nausea and encephalopathy.

Bumex®

bumetanide/Roche

0.5-mg and 1-mg scored tablets/
2-ml ampuls, 2-ml, 4-ml and 10-ml vials (0.25 mg/ml)
Before prescribing, please consult complete product information, a summary of which follows:

WARNING: Bumex (bumetanide/Roche) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dosage schedule have to be adjusted to the individual patient's needs. (See under DOSAGE AND ADMINISTRATION in complete product information.)

INDICATIONS AND USAGE: Edema associated with congestive heart failure, hepatic and renal disease, including the nephrotic syndrome.
Almost equal diuretic response occurs after oral and parenteral administration of Bumex. If impaired gastrointestinal absorption is suspected or oral administration is not practical, Bumex should be given by the intramuscular or intravenous route.
Successful treatment with Bumex following instances of allergic reactions to furosemide suggests a lack of cross-sensitivity.
CONTRAINDICATIONS: Anuria. Hypersensitivity and in patients in hepatic coma or in states of severe electrolyte depletion. Although Bumex can be used to induce diuresis in renal insufficiency, any marked increase in blood urea nitrogen or creatinine, or the development of oliguria during therapy of patients with progressive renal disease, is an indication for discontinuation of treatment.
WARNINGS: Dose should be adjusted to patient's needs. Excessive doses or too frequent administration can lead to profound water loss, electrolyte depletion, dehydration, reduction in blood volume and circulatory collapse with the possibility of vascular thrombosis and embolism, particularly in elderly patients.
Prevention of hypokalemia requires particular attention in patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis and ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, certain diarrheal states, or other states where hypokalemia is thought to represent particular added risks to the patients.
In patients with hepatic cirrhosis and ascites, sudden alterations of electrolyte balance may precipitate hepatic encephalopathy and coma. Treatment in such patients is best initiated in the hospital with small doses and careful monitoring of the patient's clinical status and electrolyte balance. Supplemental potassium and/or spironolactone may prevent hypokalemia and metabolic alkalosis in these patients.
In cats, dogs and guinea pigs, Bumex has been shown to produce ototoxicity. Since Bumex is about 40 to 60 times as potent as furosemide, it is anticipated that blood levels necessary to produce ototoxicity will rarely be achieved. The potential for ototoxicity increases with intravenous therapy, especially at high doses.
Patients allergic to sulfonamides may show hypersensitivity to Bumex.
PRECAUTIONS: Measure serum potassium periodically and add potassium supplements or potassium-sparing diuretics, if necessary. Periodic determinations of other electrolytes are advised in patients treated with high doses or for prolonged periods, particularly in those on low salt diets.
Hyperuricemia may occur. Reversible elevations of the BUN and creatinine may occur, especially with dehydration and in patients with renal insufficiency.
Bumex (bumetanide/Roche) may increase urinary calcium excretion.
Possibility of effect on glucose metabolism exists. Periodic determinations of blood sugar should be done, particularly in patients with diabetes or suspected latent diabetes.
Patients should be observed regularly for possible occurrence of blood dyscrasias, liver damage or idiosyncratic reactions.
Especially in presence of impaired renal function, use of parenterally administered Bumex should be avoided in patients to whom aminoglycoside antibiotics are also being given, except in life-threatening conditions.
Drugs with nephrotoxic potential and bumetanide should not be administered simultaneously.
Since lithium reduces renal clearance and adds a high risk of lithium toxicity, it should not be given with diuretics.
Probenecid should not be administered concurrently with Bumex (bumetanide/Roche).
Concurrent therapy with indomethacin not recommended.
Bumex may potentiate the effects of antihypertensive drugs, necessitating reduction in dosage.
Interaction studies in humans have shown no effect on digoxin blood levels.
Interaction studies in humans have shown Bumex to have no effect on warfarin metabolism or on plasma prothrombin activity.
Pregnancy: Bumex should be given to a pregnant woman only if the potential benefit justifies the potential risk to the fetus.
Bumetanide may be excreted in breast milk.
Pediatric Use: Safety and effectiveness below age 18 not established.
ADVERSE REACTIONS: Muscle cramps, dizziness, hypotension, headache and nausea, and encephalopathy (in patients with preexisting liver disease).
Less frequent clinical adverse reactions are weakness, impaired hearing, rash, pruritus, hives, electrocardiogram changes, abdominal pain, arthritic pain, musculoskeletal pain and vomiting.
Other clinical adverse reactions are vertigo, chest pain, ear discomfort, fatigue, dehydration, sweating, hyperventilation, dry mouth, upset stomach, renal failure, asterixis, itching, nipple tenderness, diarrhea, premature ejaculation and difficulty maintaining an erection.
Laboratory abnormalities reported are hyperuricemia, azotemia, hyperglycemia, increased serum creatinine, hypochloremia, hypokalemia, hyponatremia, and variations in CO_2 content, bicarbonate, phosphorus and calcium. Although manifestations of the pharmacologic action of Bumex (bumetanide/Roche), these conditions may become more pronounced by intensive therapy.
Diuresis induced by Bumex may also rarely be accompanied by changes in LDH, total serum bilirubin, serum proteins, SGOT, SGPT, alkaline phosphatase, cholesterol, creatinine clearance, deviations in hemoglobin, prothrombin time, hematocrit, platelet counts and differential counts. Increases in urinary glucose and urinary protein have also been seen.
HOW SUPPLIED: *Tablets,* 0.5 mg (light green) and 1 mg (yellow), bottles of 100 and 500; Prescription Paks of 30; Tel-E-Dose® cartons of 100. Imprint on tablets: 0.5 mg—ROCHE BUMEX 0.5; 1 mg—ROCHE BUMEX 1.
Ampuls, 2 ml, 0.25 mg/ml, boxes of ten.
Vials, 2 ml, 4 ml and 10 ml, 0.25 mg/ml, boxes of ten.

A Randomized Trial of Low-Dose Beta-Blockade Therapy for Idiopathic Dilated Cardiomyopathy

JEFFREY L. ANDERSON, MD, JOAN R. LUTZ, RN, EDWARD M. GILBERT, MD, SHERMAN G. SORENSEN, MD, FRANK G. YANOWITZ, MD, RONALD L. MENLOVE, PhD, and MARIAN BARTHOLOMEW

Beta-blockade therapy to improve survival in idiopathic dilated cardiomyopathy (IDC) has been both advocated and criticized. However, randomized studies have not been performed. Thus, 50 patients with IDC were randomized in pairs to standard therapy (C) alone or with β blockade (BB). Beta-blockade therapy with metoprolol was titrated from 12.5 to 50 mg twice daily as tolerated (final average dose, 61 mg/day). Groups were comparable in age (C, 50 ± 15 years; BB, 51 ± 13 years), gender (C, 76% male; BB, 56% male), entry functional class (C, 2.8 ± 0.8; BB, 2.7 ± 0.7), and left ventricular ejection fraction (C, 27 ± 12%; BB, 29 ± 10%). Follow-up averaged 19 months (range 1 to 38). One subject in each group was lost to follow-up. There were 3 early BB dropouts (within 2 days) due to low-output syndrome (2 patients) or fatigue (1 patient). Eleven patients died. By intention to treat, 5 BB and 6 C patients died (difference not significant). By actual treatment, 3 BB patients died, including 2 late dropouts (at 0.2, 10 and 17 months), and 8 C patients died (at 2, 9, 9, 15, 18, 24, 29 and 32 months, p = 0.12). In addition, functional evaluation on follow-up (functional class, San Diego questionnaire and exercise time) all tended to favor those receiving BB. Low-dose BB is tolerated in 80% of IDC patients on a long-term basis. Those continuing to take BB have a good prognosis. Mortality in C patients, however, is less than in some retrospective studies. The improved survival trend in the BB group may be due to selection of less ill patients and to possible protective effects of BB. A randomized multicenter study appears appropriate for definitive evaluation of survival effects of BB in IDC.

(Am J Cardiol 1985;55:471–475)

The use of β-adrenoceptor blocking agents in patients with idiopathic dilated cardiomyopathy (IDC) has been both criticized and advocated. Traditionally, β-blocking drugs have been contraindicated in this condition because of their negative inotropic effects. However, largely uncontrolled trials by the Swedish group suggest low-dose β blockade to be tolerated and beneficial.[1–4] The disease appeared to stabilize, the symptoms lessened, and mortality decreased. In contrast, others have reported negative results.[5,6] Given the poor prognosis despite therapy, the testing of new and unconventional therapies appears appropriate in IDC. We therefore performed a randomized pilot study to investigate the effects of low-dose β blockade on mortality and functional class in patients with IDC.

Methods

Hypothesis: Survival represented the primary hypothesis being tested. Using the statistics from the historically controlled study of Swedberg et al,[2] it was estimated that mortality might approach 50% in the control group at a mean of 1 to 1½ years, compared with 15% in the treated group. A total of 50 patients (25 in each group) was therefore considered adequate to demonstrate significance between the 2 groups at the $p < 0.05$ level. Functional classification represented a secondary variable on which to test the effects of therapy.

Entry criteria: Fifty consecutive adult patients evaluated at our institution with a diagnosis of IDC were recruited under an approved protocol. Patients with overt congestive heart failure were not entered until medically stabilized. IDC was confirmed by its typical echocardiographic pattern of diffuse hypokinesia together with a depressed ejection fraction (less than 40% by radionuclide ventriculography). All patients older than 30 years underwent coronary arteriography to exclude

TABLE I Entry Characteristics by Group

Variable	Control	Beta Blockade
n	25	25
Age (yr)*	50 ± 15	51 ± 13
Gender (% male)	76	56
Functional class*	2.8 ± 0.8	2.7 ± 0.7
LV ejection fraction (%)*	27 ± 12	29 ± 10
Norepinephrine (pg/ml)†	673 ± 347 (18)	547 ± 269 (14)
Average time in study (mo) (entry to June 1984)	23 ± 9	23 ± 9

* Values are expressed as mean ± standard deviation; no differences between groups are significant.
† Testing incomplete; numbers of patients given in parentheses; normal range, 65 to 320 pg/ml.
LV = left ventricular.

TABLE II Individual Death Summary (by Actual Treatment Method)

Pt. No.* & Group	Time (mo)	FC	Cause	Comment
		Beta-Blockade Group		
10BB	0.2	IV	CHF	Concomitant diltiazem
16BB	11	IV	CHF	Stopped BB 2 mo before
9BB	16	III	SD	Stopped BB 3 wk before

† Endstage CHF (died later).
BB = beta blockade; C = control; CHF = congestive heart failure; FC = New York Heart Association functional class; SD = sudden (instantaneous) cardiac death; VF = ventricular fibrillation.

coronary heart disease. Alcohol abusers and those with other secondary cardiomyopathies (amyloidosis, hemochromatosis, etc.) were excluded. Patients with firm exclusions to β-blocker treatment (asthma, advanced heart block and allergy) were also excluded.

Treatment assignment: Treatment included low-dose β blockade (metoprolol, 12.5 mg twice a day, titrated over several days up to 50 mg twice a day as tolerated) along with standard therapy, and standard therapy alone. Standard therapy included digitalis, diuretics, vasodilators and anticoagulants as needed; however, not all patients who met entry criteria had symptoms that required digitalis or diuretic therapy. Patient randomization was performed in pairs to preserve temporal balance; the first of each pair was randomly assigned to 1 treatment; the next patient was assigned to the alternative treatment. The primary outcome variable of interest was survival. Follow-up study was performed until death or to July 1984. Cause of death, instantaneous (presumed arrhythmic) or progressive heart failure was noted.

Assessment of functional class on entry and latest follow-up was made by 1 of us (JLA) according to the New York Heart Association criteria. An alternative method of functional assessment, the San Diego questionnaire, was also used for follow-up evaluation.[7] Initial exercise testing was not always possible (because of illness and scheduling problems). However, late follow-up treadmill exercise was attempted in survivors and performed either by a local physician or in the central facility. The modified Naughton protocol formed the standard test and total exercise time the end point of interest.

Statistical analysis: Analysis of survival was made both by intention to treat and actual treatment methods. For analysis by the actual treatment method, patients unable to tolerate β blockade during initial titration were considered with the control group. Three late dropouts (all after more than 6 months of β-blocking therapy) continued to be analyzed with the treatment group. Two control patients were later crossed over to long-term β-blocking therapy because of arrhythmias and then analyzed with the treatment group.

Survival data were plotted using a Kaplan-Meier graph. Comparisons were made between groups with Mantel's extension of the Kruskal-Wallis test. A chi-square analysis was also made of survival at the end of follow-up using a 2×2 contingency table. Chi-square analysis was used to compare characteristics of the 2 groups for discrete and Student t test for continuous variables. A $p < 0.05$ (2-tailed) was taken as significant.

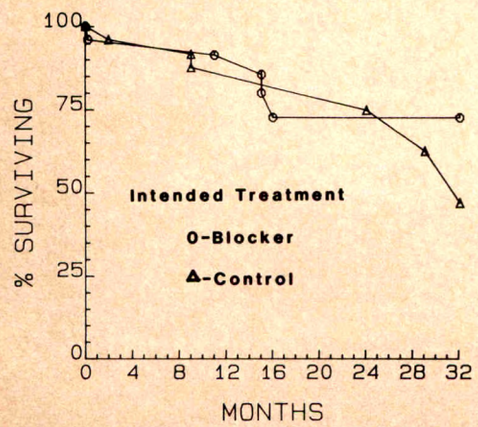

FIGURE 1. Survival curves by intention-to-treat method for control and β-blockade groups. The difference in curves is not significant.

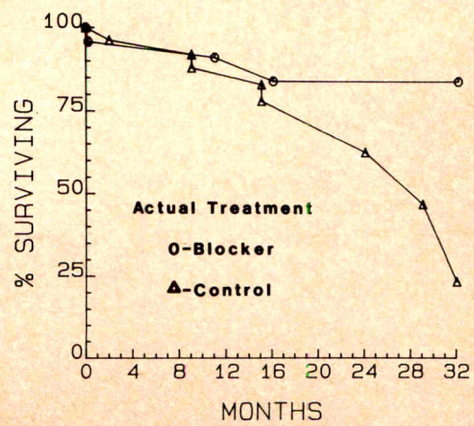

FIGURE 2. Survival curves by actual treatment method for control and β-blockade groups. The difference in curves is not significant.

TABLE III Functional Outcome Variables

Variable	Method	BB (No. of Pts)	C (No. of Pts)	p
Functional class*	Intent	2.2 ± 0.2 (25)	2.6 ± 0.1 (25)	—
	Actual	2.0 ± 0.2 (24)	2.7 ± 0.2 (26)	<0.01
Functional score† (San Diego questionnaire)	Intent	790 ± 154 (21)	1080 ± 181 (21)	—
	Actual	637 ± 136 (19)	1160 ± 173 (23)	<0.02
Heart rate at rest (beats/min)	Intent	77 ± 15 (23)	82 ± 20 (22)	—
	Actual	75 ± 12 (22)	84 ± 21 (23)	<0.06
Exercise time (min)‡	Intent	9.4 ± 1.2 (12)	8.2 ± 0.7 (16)	—
	Actual	9.3 ± 1.2 (13)	8.2 ± 0.7 (15)	—

* At last clinical evaluation (before the end of study or death) by New York Heart Association functional class.
† In survivors at last follow-up; score range = 0 to 3,000 (lowest numbers suggesting better function (see Ref. 7).
‡ Modified Naughton protocol; testing incomplete.
All values are expressed as mean ± standard error of the mean. — = difference not significant.

Results

Entry characteristics: The average age at entry was 50 ± 12 years (range 25 to 75). This age range is older than in series at transplant centers, which exclude patients older than 50 to 55 years , but is more representative of the spectrum of IDC noted clinically. Sixty-six percent of the patients were men. Entry New York Heart Association functional class averaged 2.8. Left ventricular ejection fraction at entry averaged 28%. Plasma norepinephrine was elevated. The average time from entry to evaluation at the end of the study July 1984 was identical in both groups: 23 months (range 8 to 38). Follow-up time for each subject, allowing for dropouts and deaths, averaged 19 months (range 1 to 38).

Entry characteristics by group (intention to treat) were comparable (Table I). Twenty-five were assigned to each group. The somewhat greater proportion of men in the control group was not significant.

Tolerance to beta-blocking drugs: Low-dose β blockade with metoprolol was tolerated by most patients. Initial tolerance was noted in 22 of 25 patients (88%). There were 2 late dropouts, yielding a long-term tolerance rate of 80%. The average dose of metoprolol during late follow-up was 61 mg/day (range 25 to 100). The median tolerated dose was 25 mg twice daily, but several patients used 50 mg twice daily. These doses are slightly lower than those in the Swedish experience.[1–4]

Reasons for β-blocker intolerance included 3 dropouts within the first 2 days (with 1 to 4 doses of the drug given) because of low-output syndrome in 2 and fatigue in 1. Patients who could not tolerate the drug were not rechallenged a second time. There were 2 late dropouts, at 9 and 15 months, because of progressive heart failure in 1 and pedal edema in another.

Survival trends: Survival curves for the 2 groups by the intention to treat method are presented in Figure 1. Overall, there were 5 deaths in the treatment group and 6 in the control group (difference not significant). Two patients, 1 in each group, were lost to follow-up. At 12 months, 20 patients were in the β-blockade group and 19 in the control group in ongoing follow-up. At 18 months, 10 were in the β-blockade group and 11 in the control group in ongoing follow-up. At 24 months, 7 in the β-blockade group and 7 in the control group were continuing in follow-up.

By the actual treatment method, a survival trend favoring β-blockade therapy was noted (Fig. 2). This trend became evident beyond the first year of follow-up. However, this trend did not reach statistical significance (significance level 32% by 2-tailed test, 16% by 1-tailed test).

By the intention-to-treat method, the death rate was 20% in the β-blockade group and 24% in the control group at a median of 18 months. By the actual treatment method, 13% (3 patients) of those treated with β blockade died, vs 31% (8 patients) in the control group ($p = 0.12$, χ^2) Specific deaths in the β-blockade group by actual treatment are summarized in Table IIA. The deaths occurred at 0.2, 11 and 16 months. The patients were in functional classes IV or III. The 2 in functional class IV died from progressive heart failure. In the first, who died a few days after initiating β-blockade therapy, there was concern because of a potentially negative inotropic interaction with concomitant diltiazem therapy given for angina (despite minimal coronary artery disease; spasm was questioned). In the second, β blockade was stopped 2 months before death because of progressive heart failure. In the third, death occurred suddenly 3 weeks after stopping β blockade because of peripheral edema associated with presumed progression of underlying right heart failure.

Deaths in the control group by the actual treatment method are summarized in Table IIB. These occurred at 2, 9, 9, 15, 15, 24, 29 and 32 months. Patients tended to fall into functional class IV, with 3 in functional class III or II. Five patients died suddenly and 3 died from progressive heart failure. In the first patient, the mechanism for sudden death was documented on ambulatory monitoring to be ventricular fibrillation. Patients 2 and 8 were transplanted when they became essentially moribund with failure. (Despite transplantation both died, 1 month and 3 months later.) Two of the 3 patients who had initially been intolerant of β-blockade therapy died; both were in functional class IV. Cause-specific mortality showed the strongest trend for sudden death, with 5 sudden deaths in the control group and only 1 in the β-blockade group ($p = 0.1$).

Functional outcome variables: Functional outcome trends also favored the β-blockade group (Table III).

Differences were significant by the actual treatment method, but not by the intention-to-treat method. New York Heart Association functional class at the last clinical evaluation before the end of the study or before death by the intention-to-treat method averaged 2.2 in the β-blockade group and 2.6 in the control group (difference not significant). By actual treatment, average values differed significantly, 2.0 vs 2.7 ($p < 0.01$).

A more quantitative assessment of functional class, using the San Diego questionnaire, was obtained for those who survived longer than 6 months.[7] Functional scores in this approach range from 0 to 3,000, with lower numbers suggesting better function. San Diego functional score at last evaluation averaged 790 in the β-blockade group and 1,080 in the control group ($p < 0.1$). By the actual treatment method, average values were 637 and 1,181, significantly favoring β-blocking therapy ($p < 0.02$).

Entry heart rate (mean 85 beats/min) and blood pressure (mean 118/74 mm Hg) did not differ by assigned treatment group. As expected, a lower heart rate was noted in those who received chronic low-dose β blockade on follow-up (75 ± 12 vs 84 ± 21 beats/min), but the difference did not achieve significance ($p < 0.06$). Blood pressure during therapy was similar between groups. A similar percentage of patients were given digitalis (88 and 85%), diuretic drugs (71 and 88%), vasodilators (33 and 46%), antiarrhythmic therapy (38 and 31%) and anticoagulant therapy (warfarin) (8 and 15%) in the β-blockade and control groups, respectively (actual treatment), at latest follow-up or death.

Exercise time was favorable in the β-blockade group, but follow-up was incomplete because of the large geographic distribution of referred patients, and the results were not quite significant.

Discussion

Study summary: Low-dose β blockade with metoprolol in mean doses of 25 to 50 mg twice daily was found to be tolerated both initially and on a long-term basis in 80 to 90% of patients with IDC in this prospective, controlled study. In our study, as has been observed in studies of coronary heart disease,[8,9] mortality in concurrent control patients was substantially less in prospective evaluation than had been suggested by retrospective studies. In our control patient group, a 15 to 20% per year mortality was observed, substantially lower than the 51% mortality in the first year retrospectively observed by Swedberg et al.[2] However, in patients who continued to receive long-term therapy with β blockade, a good prognosis was observed, with only a 13% mortality at a median of 18 months. This may be due to a combination of (1) protective effects of the drug, (2) a more benign course than expected for our patient group, and (3) the early selection out of high-risk patients who were intolerant of the drug. (Two of the 3 patients initially intolerant of β blockade later died from progressive heart failure.)

Previous treatment studies: In the retrospectively controlled study of Swedberg et al,[2] 24 patients treated with β blockade were compared with 13 matched historical control subjects.[2] Survival at 1 and 2 years was 83% and 69% in the β-blockade group vs 49 and 19% in the control group ($p < 0.01$). Several other studies from the same group have shown functional improvement after β-blockade therapy, including improved functional class, ejection fraction, cardiac index, apexcardiogram, and an accompanying decrease in heart rate at rest and cardiac size.[1–4] In contrast, 2 small controlled studies have questioned the positive effect of β-blockade therapy on morbidity, but the treatment periods of 30 days or less may have been too short to allow for significant treatment effects.[5,6]

Comments on mortality observations: The decreased mortality rate in our control group (15 to 20% per year) compared with that estimated from reference historical studies (25 to 50% in the first year)[2,10,11] may be a major reason for our inability to show mortality differences. In the Mayo Clinic experience (104 patients), mortality at 1 and 2 years was 32 and 46%.[10] In a recent study in 87 patients, Franciosa et al[11] observed mortality rates in severe left ventricular failure due to IDC to be 23% and 48% at 1 and 2 years. The lower control mortality rate in our study suggests that to address the mortality issue may require as many as 500 patients followed for 2 years.

A lack of a significant mortality trend may, in part, be the result of inadequately small doses. Studies in patients with coronary heart disease and hypertrophic cardiomyopathy showing improved survival have used much larger doses, averaging the equivalent of 200 mg/day or more of metoprolol.[12–14] The upward dose titration in our study was usually limited by symptoms of fatigue and dyspnea or excessive bradycardia.

Finally, the possibility of a smaller-than-expected or negligible true drug effect on survival is also consistent with our results. However, given the dismal survival results with other therapies and the lack of promising alternative approaches, it appears reasonable to pursue further the possibility of a survival advantage of β-blockade therapy.

Rationale for β-blockade therapy in dilated cardiomyopathy: The initial rationale for β blockade in IDC was to reduce tachycardia at rest.[1] Later studies indicated that an apparent beneficial effect occurred irrespective of initial heart rate.[3] The mechanism of apparent benefit is thus uncertain. Beta-adrenergic agents may exert favorable antiarrhythmic or antifibrillatory effects.[15] In coronary heart disease, several major trials have documented a beneficial effect of β-blocking drugs on survival, with the most significant reductions in mortality being in instantaneous (presumed arrhythmic) cardiac deaths.[12–15] In animal models, β-blocking drugs exert substantial antifibrillatory effects.[16] Similarly, in our study the most prominent trend was a reduction in sudden deaths. However, a trend toward a cause-specific reduction in sudden death has not been consistently noted.[2] Doses of β-blocking drugs used in the present study are also substantially less than those required for efficacy in the coronary heart disease trials.[12–14] In hypertrophic cardiomyopathy, low-dose or standard-dose β-blockade therapy has not decreased the risk of sudden death; however, substantial differences may exist in patho-

physiology between hypertrophic and dilated cardiomyopathies. Future studies should provide documentation of antiarrhythmic effects.

Two other mechanisms may be invoked to explain beneficial effects of β-blocking drugs on ventricular function. A decrease in myocardial β-adrenergic receptors (down-regulation) occurs in the failing heart, and the degree of cardiac β-receptor down-regulation can be correlated with the degree of heart failure.[17,18] Increasing levels of circulating norepinephrine and increased secretion and/or decreased norepinephrine uptake from myocardial adrenergic nerve terminals occurs, leading to increased exposure of the heart to catecholamines.[19,20] Excessive catecholamine exposure has long been known to be cardiotoxic.[20] Even lower, more "physiologic" doses of catecholamines may produce myocardial morphologic changes. Beta-blocking drugs could either prevent cardiotoxic effects of catecholamines or act to restore down-regulated, subsensitive β-adrenergic pathways to normal (or both).[18]

Limitations of the present study: This study represents a relatively small experience for establishing mortality differences, although historically controlled studies suggested the number of patients to be adequate. Lower doses of β-blocking drugs were tolerated than in some other cardiomyopathy studies.[2] The study was not blinded with respect to treatment. Patients were randomized in pairs rather than separately; this preserved temporal balance in treatment assignments. Paired observations of exercise and ventriculographic function and ambulatory monitoring could not be consistently made. However, survival observations were essentially complete and tolerance for β blockade was uniformly assessed. Clinical functional classification was also obtained in all patients.[7]

Proposal for future trials: A randomized, double-blind, multicenter study appears appropriate for further evaluation of β-blocking treatment of IDC with functional end points as a primary focus. A study of 200 to 300 patients may then yield significant results when a follow-up period of 2 years is used. Survival trends would be of additional interest. Patients should be selected for moderate to advanced disease, so as to comprise a relatively high risk group for progression. Gradual titration of the β-blocking drug should be used to achieve the highest possible dose without adverse effects. A multinational group is planning such a study.

Two-Dimensional Echocardiographically Guided Pericardiocentesis: Experience in 117 Consecutive Patients

JOHN A. CALLAHAN, MD, JAMES B. SEWARD, MD, RICK A. NISHIMURA, MD, FLETCHER A. MILLER, Jr., MD, GUY S. REEDER, MD, CLARENCE SHUB, MD, MARK J. CALLAHAN, MD, THOMAS T. SCHATTENBERG, MD, and A. JAMIL TAJIK, MD

Pericardiocentesis guided by 2-dimensional echocardiography has been used at the Mayo Clinic since April 1980. The 2-dimensional examination localizes the pericardial fluid. Particular note is made of the place on the body wall closest to the fluid. An entry track that permits puncture of the pericardial sac without damage to any vital structure is then selected for the pericardiocentesis needle. Between April 1980 and March 1984, 132 consecutive pericardiocenteses in 117 patients were done by this technique. The volume of fluid obtained ranged from 75 to 1,700 ml (mean 650). Seventy percent of the taps were done for therapy, 21% for diagnosis, and 9% for both therapy and diagnosis. A Teflon®-sheathed "intracath" needle was used to complete 80% of the pericardiocenteses. In the other 20%, a large catheter was secondarily introduced and connected to a closed drainage system. There were no deaths related to the procedure. One symptomatic pneumothorax occurred. There were 3 minor complications. Two-dimensional echocardiographic imaging of the heart and pericardial fluid permits a safe and effective means of performing pericardiocentesis. (Am J Cardiol 1985;55:476–479)

Two-dimensional (2-D) echocardiographically directed pericardiocentesis was developed and described by members of the Mayo Clinic Echocardiographic Laboratory.[1,2] Nearly all pericardiocenteses performed at our institution since 1980 have been done in this manner. Blind percutaneous pericardial puncture has been associated with significant morbidity and mortality, and it has been recommended that this procedure be abandoned.[3–7] A safer, but more invasive, technique, subxiphoid surgical pericardiotomy, has been recommended.[8–11] We report 132 consecutive 2-D echocardiographically directed pericardiocenteses performed between April 1980 and March 1984.

Methods

Patients who had 2-D echocardiographically guided pericardiocentesis at our institution between April 1980 and March 1984 are the subjects of this report. Of the 117 patients, 52 were female and 65 were male. Fifteen of the patients had 2 separate procedures, so that 132 procedures were performed. The mean age was 50 years (range 1 to 82).

This experience represents consecutive cases of echocardiographically directed pericardiocentesis over a 4-year period. Because the number of patients increased during the study period, clinical acceptance of this new technique is implied. Pericardiocenteses performed before the echocardiographic era were not methodically catalogued. Therefore, an institutional comparison of results is not possible. We rely on published series to determine comparative risks and effectiveness (Table I).

Results

Two-dimensional echocardiographic findings: *Fluid location:* Fluid extended circumferentially in 103 instances (79%) and was loculated in 27 instances (21%).

Intrafluid strands, masses and particles: Strands were seen within the pericardial sac in 33 instances (25%). Mass lesions were noted in 4 patients (1 with *Hemophilus influenzae* infective pericarditis and 3 with metastatic malignancy). Particulate matter in great abundance was observed by 2-D echocardiography and removed by catheter in 1 infective case (*Moraxella*).

Causes of the effusion: The causes of effusion and their incidences were malignancy in 36%; unknown

cause in 31%; cardiac surgery in 16%; infection in 7%; and miscellaneous conditions (including trauma, rheumatoid arthritis, congestive heart failure and complications of anticoagulant therapy) in 10%. The volume of fluid obtained ranged from 75 to 1,700 ml (mean 650).

Indications for pericardiocentesis: Seventy percent of the taps were done for therapeutic reasons, 21% for diagnostic reasons and 9% for both.

Therapeutic: Symptomatic effusions (95 cases) included clinical tamponade, hypotension and dyspnea as well as "pretamponade," in which the effusion was large and caused clinical concern for the patient's safety (volume obtained, 75 to 1,700 ml, mean 650).

Diagnostic: The 26 diagnostic taps were characterized by smaller volumes (30 to 850 ml, mean 297). In 2 instances, echocardiographic contrast injections were made to verify the location of the needle cannula.[12,13]

Diagnostic and therapeutic: Both diagnostic and therapeutic indications were present in 11 cases (volume, 80 to 1,300 ml; mean 445).

Technique of 2-dimensional echocardiographically guided pericardiocentesis: *Patient positioning:* The patient was supine with the head slightly elevated or in the left lateral decubitus position in more than 90% of instances. A few patients could not assume a supine position because of dyspnea. In these patients both the echocardiographic examination and the pericardiocentesis were done with the patient sitting upright.

Puncture site: The site of needle entry was determined by 2-D echocardiographic examination. The ideal site was that at which the fluid was closest to the transducer and from which a needle track avoided the heart or any underlying vital structures. Subcostal entry was selected in 33 cases (25%), whereas in 85 cases (64%), a chest wall puncture site was chosen. In 14 of our initial cases (11%) the puncture site was not specified. The chest wall sites selected included left parasternal (11 patients), midclavicular line (6), anterior axillary line (fifth to seventh intercostal space) (61), posterior chest (1), and right parasternal (3). In 3 instances of loculated effusion, 2 entry sites were used.

Needle type: All pericardiocenteses were started with a short (2- to 4-cm) 16- or 18-gauge, Teflon®-sheathed, "intracath" needle. When the pericardial sac was entered and the first fluid was withdrawn, the Teflon sheath was advanced and the steel core was withdrawn. Seventy-eight percent of the pericardiocenteses were completed with only this small sheath.

Intrapericardial catheter: A large drainage catheter was used in 29 instances (22%). In 2 of the initial patients, only a 6 or 7Fr Teflon sheath (Cordis) was used. In 27 cases, a 6 or 7Fr pigtail catheter was inserted through the sheath into the pericardial sac. The technique involved introducing a short, flexible (0.035 mm) wire through the Teflon "intracath" sheath and then withdrawing the sheath. A dilator and introducer sheath (6Fr or 8Fr Cordis) were advanced over the wire into the pericardial sac. A pigtail catheter was introduced through this sheath. The catheter was attached to a closed system for continuous drainage, and a small amount of heparinized saline solution was injected periodically for flushing. The catheter system remained within the pericardial sac for 1 to 13 days without complication. Antibiotics were administered intrapericardially in three patients with infective pericarditis.

TABLE I Complications of Blind Percutaneous Puncture Method for Pericardiocentesis Reported in Recent Literature

First Author	Year	Procedures (n)	Complications (%)	Deaths (%)
Morin[3] (review)	1976	86		19
Krikorian[4]	1978	123		4
Kwasnik[5]	1978	34	15	0
Wong[6]	1979	52	15	2
Guberman[7]	1981	46	7	4

Complications: *Major:* No patient died. One patient (0.76%) with a previous right pneumonectomy for squamous cell carcinoma sustained a symptomatic pneumothorax during the infiltration of local anesthetic. The entry site was the anterior chest wall, near the cardiac apex. The pneumothorax was presumed to be secondary to rupture of an emphysematous bleb. A chest tube reexpanded the lung, and the pericardiocentesis was performed without incident. Three months later, a second pericardiocentesis was performed without difficulty through a subcostal entry site.

Minor: One patient had vasovagal syncope during needle insertion and refused to continue the procedure. In 2 patients, the right ventricular cavity was entered with the small sheathed needle (16 gauge) without complication. Both procedures were completed without incident. Pneumopericardium, observed in 1 patient, was without clinical consequence.

Pericardial fluid: *Amount:* One patient refused to proceed and no fluid was obtained. In 1 patient with a small effusion, no fluid was obtained. In 2 patients, only a few milliliters of fluid were obtained; 1 had thick, purulent material from which staphylococcal organisms were cultured, and the other had a clotted bloody effusion associated with a complication of anticoagulant therapy. In 2 patients, most of the pericardial effusion escaped into the pleural space, relieving tamponade. In the remaining 126 taps, the amount of fluid ranged from 75 to 1,700 ml (mean 650).

Appearance: Pericardial fluid was serous (27 patients), serosanguineous (blood-tinged or grossly bloody) (99), chylous (1), and purulent (4). Of the 99 bloody effusions, 46% were related to malignant lesions, 15% to cardiac surgery, 18% to unknown causes, 5% to infection, 4% to trauma, 4% to rheumatoid arthritis and 8% to miscellaneous conditions. Of the 27 straw-colored effusions, 33% were related to malignant lesions, 22% to cardiac surgery, 30% to unknown causes, 7% to infection, 3% to rheumatoid arthritis, 3% to congestive heart failure and 2% to miscellaneous conditions. In both groups of patients, those with straw-colored and those with bloody effusions, the miscellaneous causes consisted of myocardial infarction, trauma, rheumatoid arthritis, congestive heart failure and radiation trauma. The most unusual appearance was secondary to a gram-negative bacillus (*Moraxella*), which produced a bright yellow fluid.

Analysis: Pericardial fluid was taken under sterile conditions and uniformly sent to the microbiology

laboratory for examination for anaerobic and aerobic bacteria, tuberculosis and fungi. Among 8 taps for suspected infective pericarditis, 3 cultures were positive (beta streptococcus, *Escherichia coli* and *Hemophilus influenzae*). One patient with a negative fluid culture had a gram-negative bacillus on Gram's stain. *Moraxella* grew on a culture of pericardial material obtained at surgery 10 days later. In 3 patients with staphylococcal septicemia, cultures of pericardial fluid were negative. One patient had acute histoplasmosis with negative cultures of fluid.

Cytology: Cytologic study of the pericardial fluid was not requested in cases of trauma, cardiac surgery or known malignancy of the pericardium. It was done in 82 cases. Cytologic results were uniformly negative in the effusions unrelated to malignancy. In the effusions caused by or related to carcinoma, there were 24 positive and 24 negative cytologic findings. Among the patients with negative findings late in the course of treatment were 5 with squamous carcinoma or adenocarcinoma of the lung. Five patients had small-cell carcinoma of the lung, 5 had lymphoma, 2 had leukemia and 2 had metastatic breast cancer. Three of the patients with lymphoma had atypical lymphocytes in the pericardial fluid. One patient with metastatic breast cancer had a pericardiectomy, and no cancer could be found in the surgical specimen. Five additional patients with negative cytologic results had metastatic melanoma, osteogenic sarcoma, mucus-producing adenocarcinoma, thymoma and primary angiosarcoma of the heart. Nonmalignant pericardial disease in the cancer patients remained possible[14] but could not be proved in cases without postmortem examinations.

Surgical intervention: Twenty-nine patients had subsequent partial or complete pericardiectomy procedures for recurrent effusion, for chronic recurrent pericarditis, or for effusive-constrictive pericarditis.

Four patients had limited surgical procedures. Two had open biopsy of the pericardium and drainage of the fluid, and 2 had pericardial window procedures. All 4 patients required subsequent interventions for reaccumulated pericardial fluid. Three had 2-D echocardiographically guided pericardiocentesis and 1 had a total pericardiectomy from 2 days to 4 months after the limited surgical intervention.

Pericardiocentesis in extreme situations: Three patients had 2-D echocardiographically guided pericardiocentesis as part of a heroic lifesaving effort. In 1 patient a small amount of pericardial fluid was removed in the course of prolonged cardiopulmonary resuscitation. The outcome was not changed, but the tap was not harmful. In another patient, rupture of the heart occurred in the course of myocardial infarction. His condition improved by pericardiocentesis for several hours, but he later died. In the third patient, in whom spontaneous rupture of the ascending aorta occurred, 2 pigtail catheters were placed in the pericardial sac so that the patient could be transported to the operating room. The patient did not survive.

Discussion

The conventional, standard method of pericardiocentesis uses a subcostal, blind-puncture pericardiotomy technique essentially as described by Marfan.[15] Reports of this approach have continued to reveal significant complications and mortality.[3–7,16,17] It has been strongly suggested that the blind procedure be abandoned in favor of the safer subcostal, surgical pericardiotomy.[8–11]

Echocardiography has been established as the diagnostic procedure of choice in pericardial effusion.[18–21] The use of echocardiography in the clinical management of pericardial effusion seemed intuitive, and echocardiographic guidance for pericardiocentesis has been suggested by several investigators. In 1973, a special M-mode transducer was designed to guide the needle into the pericardial effusion.[22] Visualization of a pericardiocentesis needle by 2-D echocardiography was reported in 1978.[21] Contrast echocardiographic techniques to identify the location of the tip of the pericardiocentesis needle within the pericardial sac have been described.[12,13] Other investigators, recognizing the inherent safety of the method, have suggested using 2-D echocardiography to guide the placement of a pericardiocentesis needle.[23–26] Despite these reports, the usefulness of 2-D echocardiographically directed pericardiocentesis has not been realized. In practice, echocardiography is almost universally used to diagnose pericardial effusion, but the pericardiocentesis procedure is done by the blind percutaneous (subcostal) puncture technique or by surgical (subcostal) pericardiotomy.

We have described a technique in which the 2-D echocardiogram is used to select the optimal pericardiocentesis entry site.[1] The site chosen is that where fluid is closest to the skin and where the needle track will most effectively avoid any vital structures. Because ultrasound does not travel through air, lung tissue can be avoided. We make detailed observations with the ultrasound beam path, which is used to select the direction of the needle. The needle is passed into the fluid-containing sac without continuous echocardiographic visualization. In a few early cases, the needle was attached directly to a transducer for continuous monitoring, but we found this technique time-consuming and unnecessary. The removal of fluid is monitored intermittently by 2-D echocardiography from a remote transducer position. Because we use a Teflon-sheathed needle, we have not used electrocardiographic monitoring.[27]

The attractiveness of 2-D echocardiographically directed pericardiocentesis rests on 3 factors: It is simple, safe and effective. The simplicity has been described. The safety of the procedure is related to the instruments. The 2-D echocardiographic transducer is the operator's guide to the shortest distance from skin to fluid, allowing avoidance of the heart and other vital structures and permitting selection of the shortest and safest route to the fluid-containing space. Thus, pericardiocentesis can be performed by percutaneous needle puncture, using a short Teflon-sheathed needle, avoiding the morbidity, risk and expense of surgery and anesthesia. The effectiveness of the procedure is related in large measure to its versatility. It can easily be carried out as an emergency procedure and is complete enough to satisfy routine diagnostic needs. The small Teflon-

sheathed needle was adequate for 80% of taps. In less than 1% of cases, clot or thick, purulent material precluded effective removal of fluid.

Placement of a catheter in the pericardial sac has been described, with variations in technique, since 1955.[28] In 1966, Nordenström[29] described checking the position of an introducing system in the pericardium by visualizing small injections of contrast medium by fluoroscopy. In 1983,[30] a similar technique with a Seldinger wire technique without visualization was described. The placement of pigtail catheters by fluoroscopic guidance in children has been recommended.[31] Our common practice has been to place large drainage catheters in the pericardium by 2-D echocardiographic guidance with use of a percutaneous introducer system. A Teflon (6 or 7Fr Cordis) or pigtail catheter (5 or 7Fr) attached to a closed system was placed in 24 patients and remained in place for 1 to 13 days without complication.

Partial or complete pericardiectomy was used in this series for constrictive pericarditis, recurrent pericardial effusion, refractory infection or removal of a mass of clotted blood. In the 2-D echocardiographically directed pericardiocentesis done for therapeutic reasons (70%), the initial treatment by pericardiocentesis was effective and satisfactory in all but 3 instances. In the pericardiocenteses done for diagnosis (30%), subsequent surgical biopsy gave additional correct information in 3 cases. In this series, 2-D echocardiographically directed pericardiocentesis in the initial procedure was as effective as surgery for therapy and diagnosis.

Magnetic Resonance Imaging of Constrictive Pericardial Disease

RENATE L. SOULEN, MD, DAVID D. STARK, MD, and CHARLES B. HIGGINS, MD

Gated magnetic resonance imaging of 5 patients with suspected constrictive pericardial disease was performed using a superconducting magnet operating at 0.35 Tesla. Results were compared with those of echocardiography and hemodynamic measurements in all patients, with chest films in 5, computerized tomography in 2 and with histologic findings in 3. Pericardial thickness exceeded 5 mm in 4 patients and was 5 mm in 1 patient. Absence of magnetic resonance signal from the thickened pericardium was observed with extensive calcific deposits, and increased intensity of the thickened pericardium was associated with inflammatory disease. Dilatation of the right atrium, venae cavae and hepatic veins, and right ventricular narrowing was observed in all patients. The ventricular septum was straight in all patients. Magnetic resonance imaging allows both measurement of pericardial thickness and depicts internal cardiac anatomy without exposure to radiation or use of contrast medium. Satisfactory imaging with a large field of view can be performed in the presence of lung disease, thoracic deformity or surgical "hardware"—conditions that limit echocardiography and computerized tomography. The inherently 3-dimensional data permit imaging in any plane without loss of resolution. Thus, magnetic resonance appears to be the noninvasive method of choice for the diagnosis of constrictive pericardial disease.

(Am J Cardiol 1985;55:480–484)

The diagnosis of constrictive pericardial disease, and particularly its distinction from restrictive cardiomyopathy, remains a difficult clinical task.[1–5] Both entities result in restriction of ventricular filling, so it is not surprising that physical examination, noninvasive tests and even cardiac catheterization may fail to differentiate them.[1] Computerized tomography (CT), which has the capacity to define pericardial thickness, has proven valuable in this setting.[2–5] More recently, magnetic resonance imaging has also been shown to define pericardial thickness.[6] We report our experience with magnetic resonance imaging in the diagnosis of constrictive pericardial disease.

Methods

Five patients with clinical suspicion of constrictive pericardial disease were studied. One had prior cardiac surgery; 1 had prior mediastinal irradiation and chemotherapy; 1 had chronic renal failure with uremia; 2 had a positive tuberculin test result but no history of active tuberculosis. Equalization of end-diastolic pressures was found at cardiac catheterization in all 5 patients; tracking of these pressures with exercise was seen in patient 4. Prominent x and y descent in the right atrial pulse wave was seen in patients 1 and 3, and the "square-root" ventricular wave form in patient 2. Constrictive pericardial disease was considered the most likely diagnosis at the conclusion of catheterization in each patient.

Gated magnetic resonance imaging was performed using a superconducting magnet operating at 0.35 Tesla (hydrogen resonance frequency 15 MHz). The imager has been described.[7] The radiofrequency pulses and gradient pulses were synchronized to specific phases of the cardiac cycle using electrocardiographic gating. The gating technique used in our laboratory has been described in detail.[8] A spin echo pulsing sequence was used with pulse repetition interval (TR) determined by the cardiac rate and with sampling intervals (TE) of 28 and 56 ms. Imaging was performed using the multislice technique, with 5 slices obtained per sequence, each separated in time by 100 ms. The first image in each multislice series was synchronized to end-diastole and each subsequent slice corresponded to 100 ms later in the cardiac cycle. Axial images were obtained in all patients; coronal images were added in 3. Using the multislice technique, the time required to obtain a set of 5 slice is 5.5 to 8.5 minutes, depending on the subject's heart rate. Because of the long time for data acquisition, patient cooperation is important. Although respiratory motion does not usually degrade the images, patient movement during the study causes severe deterioration in image quality.

Magnetic resonance images were interpreted indepen-

D = dilated; HV = hepatic veins; IVC = inferior vena cava; LA = left atrium; LV = left ventricle; LVH = left ventricular hypertrophy; N = normal; PCa# = pericardial calcification; PE = pericardial effusion; RA = right atrium; RV = right ventricle; RVH = right ventricular hypertrophy; SVC = superior vena cava; TP = thickened pericardia; + = present or positive; 0 = absent or negative; * = not done.

dently. Data from these images were then compared with 2-dimensional and M-mode echocardiographic, hemodynamic and angiographic data in all 5 patients, with CT in 2 patients, and with operative/histologic findings in 3 patients.

Results

The causes of pericardial constriction and data from the imaging studies are listed in Table I.

Magnetic resonance: Constrictive pericarditis was characterized by pericardial thickening, which exceeded 5 mm in 4 patients and was a maximum of 5 mm in 1 patients. Thickening was diffuse, though not uniform, in 4 of these patients. One patient, who underwent prior pericardial stripping, had thickened pericardium over the right atrium only, while the right ventricle was adherent to and compressed by the sternum (Fig. 1). Intensity of the thickened pericardium varied from high, most striking in the patient with uremic pericarditis (Fig. 2), to absence of signal in areas shown by other studies to be calcified (Fig. 3). Pericardial effusion was seen only in the patient with uremia, producing a near-absent signal in contradistinction to the surrounding high-intensity pericardial image and the extensive adhesions seen coursing between the visceral and parietal layers.

Ventricular size was normal or small in all patients with constriction. Right ventricular shape was tubular and narrowed (Fig. 1, 2 and 3) in each patient. Two patients had concentric left ventricular hypertrophy (wall thickness greater than 12 mm at end-diastole), 1 patient had focal left ventricular thickening, and 1 had slight left atrial enlargement. The interventricular septum was straight in all patients. Dilatation of the cavae and hepatic veins was present in all 5 patients with constrictive pericardial disease. Pleural effusions were observed in 3 patients, bilateral in 2; the effusions showed increased intensity on the second spin echo image in each case.

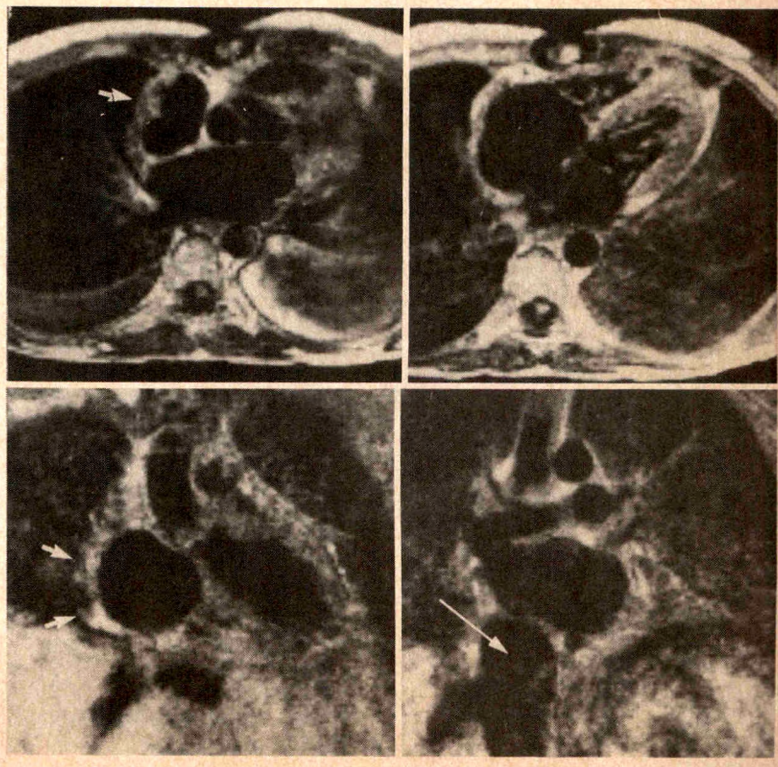

FIGURE 1. Constriction postradiation and partial pericardial stripping. Axial (**top**) and coronal (**bottom**) images show the pericardium around the enlarged right atrium to be increased both in thickness and intensity (**arrowheads**). The right ventricle is adherent to the sternum (**top right**) and somewhat cylindrical. The interventricular septum is straight. The dilated inferior vena cava (**arrow**) and hepatic veins are particularly well shown in the coronal views. Bilateral pleural effusions are present.

Comparative studies: Echocardiography identified pericardial thickening in 3 patients and pericardial fluid in 2. The magnitude of pericardial thickening in the patient with uremia was considered mild and pericardial adhesions were not found. Impaired penetration of the sound beam led to technically limited studies in the 2 patients with extensive pericardial calcification. Ventricular size was considered normal in all 5 patients with constrictive pericardial disease, although left ventricular function was depressed in 1 of these patients. Right atrial enlargement was appreciated in only 2 of these patients, although increased caliber of the inferior vena cava without respiratory variation was seen in all 5.

CT revealed thickened pericardium in the 2 patients with constrictive pericardial disease studied by CT, although evaluation of cardiac borders was obscured in 1 patient by artifacts from metallic clips. The extensive pericardial calcification in one of these patients was well demonstrated (Fig. 3).

Follow-up: Three patients underwent surgery for pericardial resection. Magnetic resonance correctly identified the pathologic entity in all 3.

Discussion

The distinction between constrictive pericarditis and restrictive cardiomyopathy is critical because the treatment of choice for the former is surgical and for the latter, medical. Pericardiectomy results in long-term improvement in 66% of patients with constrictive pericarditis.[9]

Of the functional and structural abnormalities demonstrated by noninvasive imaging techniques in constrictive pericardial disease, pericardial thickening is the prime finding that supports this diagnosis; however, thickened pericardium is not synonymous with constriction. Pericardial thickness is not reliably measured by echocardiography in the absence of fluid on both sides (pericardial and pleural)[10]; pericardial calcification produces a sonic barrier. However, echocardiography does provide important information regarding chamber size and function and respiratory variations in chamber and vena caval dimensions. It is also inexpensive and readily applied even in critically ill patients. CT permits measurement of pericardial thickness around the entire cardiac perimeter irrespective of the presence or absence of calcification, and thus is useful both in the diagnosis of constrictive pericardial disease and as a guide to adequate pericardiectomy.[2–6] The mean CT width of the thinnest portion of normal pericardium has been reported as 2.0 ± 0.6 mm in male and 2.3 ± 0.5 in female patients, with no normal measurement greater than 4 mm in either male or female patients.[11] However, small pericardial effusions are sometimes difficult to distinguish from pericardial thickening.[12] In the presence of appropriate pathophysiology, a CT measurement of 2 mm has been used by Moncada[2] and Isner[3,4] and their co-workers as the discriminating thickness between constrictive pericarditis (>2 mm) and restrictive cardiomyopathy (less than 2 mm). The pericardial thicknesses in our patients are in keeping with such classification.

Magnetic resonance, without patient irradiation, provides the same opportunity to measure pericardial thickness around the entire heart. Although nongated

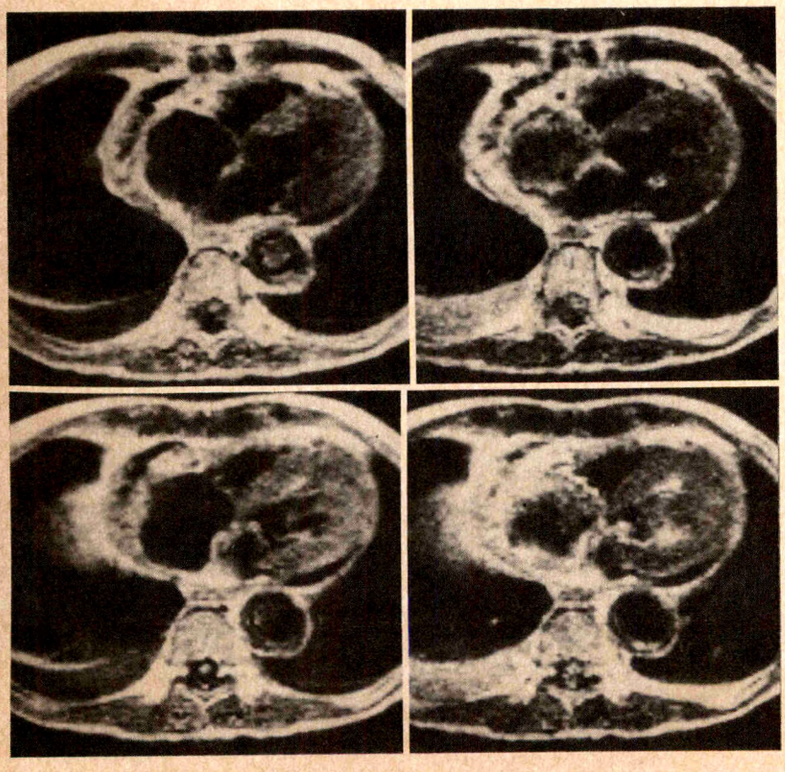

FIGURE 2. Constrictive uremic pericarditis. First (**left**) and second (**right**) spin echo images sequential axial images show irregularly thickened visceral and parietal pericardium of increased intensity, separated by low-intensity fluid, surrounding the enlarged right atrium. The second echo image shows a further increase in intensity, in keeping with a long T2. The right ventricle is normal in size, the left ventricle hypertrophied, the septum straight. Pericardial fluid is also seen behind the left ventricle, where abnormalities of the pericardium itself are less marked. Bilateral pleural effusions are present.

CT is effective for defining pericardial thickness, electrocardiographic gating is essential to adequately depict the pericardium on magnetic resonance images. The spatial resolution of magnetic resonance used in the current study was 1.7 mm, whereas that of current CT scanners is 1 mm or less. In contradistinction to the situation in CT, hemostatic clips and other metallic sequelae of cardiac surgery produce no artifacts on magnetic resonance images. Differences in signal intensity, T1 and T2 measurements can be used to characterize the thickened pericardium and have the potential for defining a specific cause. Strikingly high intensity has been reported in patients with uremic pericarditis[6] and attributed to increased tissue water content associated with an inflammatory process. The histologic findings in 1 of our patients support this hypothesis. The cause of the increased intensity in patient 2 is uncertain. The near-absent signal in the inner pericardial rim of patient 4 correlates very well with the extensive calcification seen in the same areas on CT (Fig. 3) and is in keeping with the paucity of mobile protons in this tissue. However, because fibrotic tissue also produces low-intensity signals, magnetic resonance intensity cannot match CT for the detection of pericardial calcification.

Focal deformity of the right ventricular contour and acute angulation of the distal interventricular septum on CT scans have been described by Doppman et al[5] as characteristic of constriction, but these findings have not been corroborated by others[2–4] and were not seen in our patients. Instead, constriction was manifested by right ventricular narrowing, resulting in a tubular-shaped chamber of modest size, in contrast to a disproportionately dilated right atrium, inferior vena cava and hepatic veins.

Thus, magnetic resonance imaging permits the

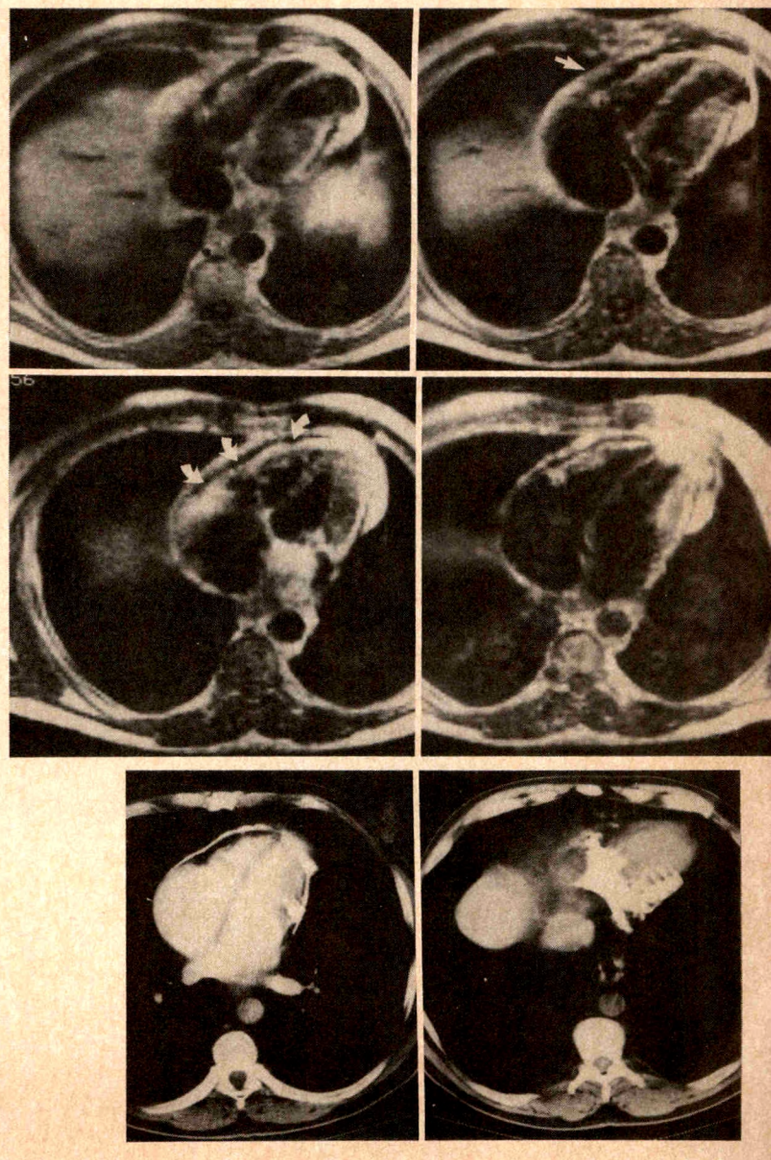

FIGURE 3. Calcific constrictive pericarditis. Multilevel axial magnetic resonance images (**top** and **middle**) reveal a thickened pericardium characterized by 2 layers. A wide, low-intensity rim (**arrowheads**) just above the epicardial fat is attributed to the calcification, well shown on computed tomography (CT). Extension of this calcification into a region of focal left ventricular wall thickening is clear on both magnetic resonance (**middle right**) and contrast-enhanced CT scan (**lower right**); the calcification in the posterior atrioventricular groove seen on CT (**lower left**) was not appreciated on magnetic resonance. A peripheral layer of medium intensity (**arrow**) is best seen adjacent to the right ventricle (**top right**). Both ventricles are narrowed and elongated (**top left** and **right, middle** and **lower right**); the septum is straight; the right atrium is dilated.

measurements of pericardial thickness and also displays the alterations in the size of cardiac chamber indicative of pericardial constrictive disease. This early experience suggests that magnetic resonance may be the preferred imaging technique for suspected pericardial constrictive disease.

The King of Hearts: Analysis of 23 Patients with Hearts Weighing 1,000 Grams or More

WILLIAM C. ROBERTS, MD, and MICHAEL J. PODOLAK, BSE*

Certain clinical and morphologic features are described in 23 patients in whom the heart at necropsy weighed at least 1,000 g (mean 1,106). The heart weight to body weight ratio ranged from 1.2 to 2.7 (normal 0.40). The 23 patients were derived from examination of the hearts of 7,671 patients with various cardiovascular disorders over a 25-year period. The massive cardiomegaly was the result of aortic regurgitation in 14 patients (61%): isolated in 8, associated with mitral regurgitation in 4, and with ventricular septal defect in 2. Three others (13%) had combined aortic valve stenosis and aortic regurgitation and 1 patient (4%) had mitral stenosis and regurgitation and mild aortic stenosis. Four patients (17%) had hypertrophic cardiomyopathy, and 1 patient (4%) had ventricular septal defect with mitral stenosis. They were 20 to 64 years old (mean 42) and 21 (91%) were men. Four patients at necropsy had 1 or more major coronary arteries narrowed more than 75% in cross-sectional area by atherosclerotic plaques, and only 4 patients had grossly visible left ventricular (LV) scars, 2 of whom had insignificant coronary narrowing. Examination of electrocardiograms in 17 of the 23 patients disclosed that Sokolow-Lyon criteria for LV hypertrophy was achieved in only 12 patients (71%) and Romhilt-Holt QRS voltage criteria faired even worse. Total 12-lead QRS voltage was more than 175 mm (10 mm = 1 mV) in 16 patients (94%) and it was more than 250 mm in 13 patients (76%). Total 12-lead QRS voltage in 17 patients ranged from 140 to 601 mm (mean 323). Measurement of the sum of the 12-lead QRS voltage may be quite useful in diagnosing LV hypertrophy by electrocardiogram.

(Am J Cardiol 1985;55:485–494)

The upper limit of the normal heart weight in women is about 350 g and for men, about 400 g. Hearts that weigh 1,000 g or more* in human beings are rare. During the past 25 years one of us (WCR) has examined at necropsy the hearts of 23 patients in whom the heart weighed at least 1,000 g (>2.5 times normal weight). Certain clinical and morphologic findings in these 23 patients are described in this report.

Methods

From July 1, 1959, to July 30, 1984, the hearts of 7,671 patients with cardiovascular disease were examined at the National Institutes of Health by 1 of us (WCR). The file of each was reexamined and the records of those in whom the heart weight was recorded as at least 1,000 g were pulled. Thirty-two patients had hearts that weighed more than 1,000 g recorded in the necropsy protocol. Upon review of the records and on reexamination of most of the hearts it was apparent that the weights in 9 of the 32 patients were inaccurately recorded because ascending aorta or parietal pericardium or other tissues were still attached to the heart, and although the hearts weighed more than 900 g, they weighed less than 1,000 g. Thus, 23 patients remained in whom the heart itself weighed at least 1,000 g. In 21 of the 23 patients the weights were those recorded by 1 of us (WCR). In each, the weight was that obtained after the heart had been fixed in 10% formalin for about 48 hours, after the main right and left pulmonary arteries, ascending aorta (2 cm cephalad to the sinotubular junction), all parietal pericardium and all intracardiac clot or thrombus had been removed from the heart itself. The scale used to weigh most of the hearts was a Mettler P1210, a scale with a range from 10 mg to 1,200 g. A different scale was used for the 4 hearts that weighed more than 1,200 g.

The clinical and morphologic records in all 23 patients were then examined. The hearts in 15 of the 23 patients were reexamined.

Results

The data obtained in the 23 patients are recorded in Tables I, II and III. The patients were 29 to 64 years old

* Atrial fibrillation: †atrioventricular junctional rhythm.
AR = aortic regurgitation; bpm = beats per minute; HC = hypertrophic cardiomyopathy; MR = mitral regurgitation; MS = mitral stenosis; VR = ventricular rate; VSD = ventricular septal defect.

(mean 42); 21 (91%) were men and 2 (9%) were women. Cardiac conditions producing the massive cardiomegaly were: (1) pure *aortic regurgitation* (AR) in 14 patients (isolated in 8, associated with mitral regurgitation [MR] in 4 and with ventricular septal defect [VSD] in 2); (2) *combined aortic stenosis (AS) and AR* in 3; (3) *hypertrophic cardiomyopathy* in 4; (4) *combined mitral stenosis (with MR) and AS* in 1 patient; and (5) *VSD with mitral stenosis* (parachute mitral valve) in 1. Of the 8 patients with isolated pure AR, the origin of the valve disease was infective endocarditis that healed in 2[1] (patients 4 and 6, Table I) (Fig. 1), congenitally bicuspid aortic valve that never was the site of infection in 1 (patient 6),[2] uncertain in 2 (patients 1 and 5), rheumatic in 1 patient (patient 2), ankylosing spondylitis in 1 (patient 3),[3] and syphilis in 1 (patient 8) (Fig. 2).[4] Of the 4 patients with combined AR and MR, the cause was rheumatic in 3 (patients 9, 11 and 12) and infective endocarditis that healed in 1 (patient 10) (Fig. 3). The AR in the 2 patients with VSD (nos. 13 and 14) resulted from prolapse of 1 of the 3 aortic valve cusps, with superimposed infective endocarditis that healed in 1 of the patients (no. 14) (Fig. 4 and 5). One patient (no. 14) with AR plus VSD also had a small (20-mm Hg) peak systolic pressure gradient between left ventricle and systemic artery (Fig. 5). Two patients (nos. 15 and 16) had congenitally bicuspid aortic valves causing combined aortic valve stenosis and regurgitation (Fig. 6)[5]; the stenosis was the dominant hemodynamic lesion in 1 (patient 17) and he had a bicuspid aortic valve (Fig. 7). The cause of the combined mitral and aortic valve stenosis in patient 18 was rheumatic. The hypertrophic cardiomyopathy in patients 19 to 22 was congenital in origin (Fig. 8). Patient 23 obviously had congenital heart disease (Fig. 9).

Electrocardiograms were available for examination in 17 patients (Table II, Fig. 1, 3, 5 and 6). Twelve had had valve replacement operations; the electrocardio-

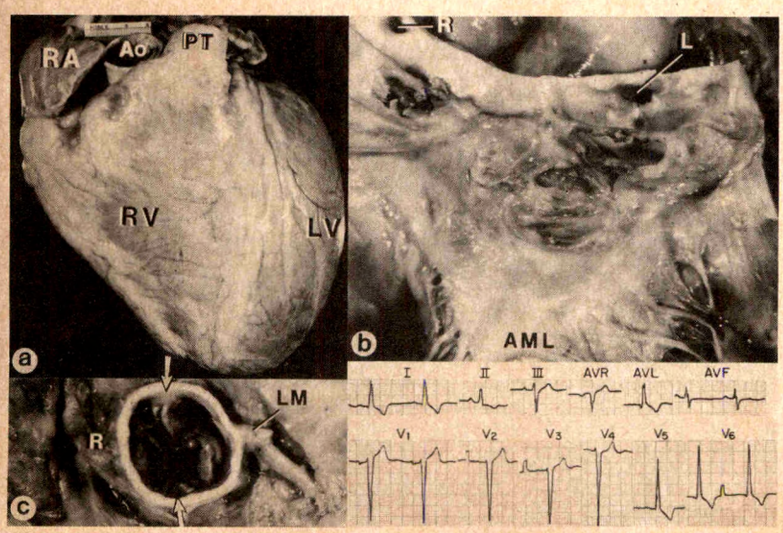

FIGURE 1. Patient 4 in Table I. Heart, weighing 1,010 g, and electrocardiogram from a 39-year-old man (A69-254) who had active infective endocarditis on a bicuspid aortic valve at age 24 years and aortic regurgitation thereafter. He refused operative treatment. He died suddenly while playing golf. **a,** exterior of heart. Ao = ascending aorta; LV = left ventricle; PT = pulmonary trunk; RA = right atrium; RV = right ventricle. **b,** opened aortic valve. Each cusp is perforated and the margins of the perforations contain small calcific deposits. AML = anterior mitral leaflet; L and R = left and right coronary ostia. **c,** congenitally bicuspid aortic valve from above. The **arrows** designate the 2 commissures. LM = left main and R = right coronary artery. The QRS voltage in the precordial leads is enormous. A strain pattern is present.

gram analyzed was recorded within the month preceding operation. Seven of these 12 patients died within 76 days (median 3) of operation; the other 5 patients died 12, 12, 37, 52 and 53 months (mean 33) after operation. In the latter 5 patients electrocardiograms were available for examination 12, 7, 22, 52 and 31 months (mean 25), respectively, after valve replacement.

A single QRS complex was measured in each lead in the 17 patients (Fig. 10). The total 12-lead QRS voltage ranged from 140 to 601 mm (mean 323) (10 mm = 1 mV); in 16 patients (94%) this voltage was more than 175 mm and in 13 (17%), more than 250 mm. In 5 patients with isolated severe AR, the total 12-lead QRS voltage ranged from 179 to 414 mm (mean 300); in 4 patients with combined AR and MR, it was 214 to 414 (mean 321); in 2 patients with AR plus VSD, it was 365 and 397 mm; in 2 patients (nos. 15 and 16) with AR plus AS, it was 209 and 287 mm, and in 2 patients with hypertrophic cardiomyopathy, it was 405 and 601 mm. The mean QRS voltage in each of the 12 leads in each of the 17 patients was 27 mm. The individual and mean QRS amplitudes in each of the 12 leads in the 17 patients are

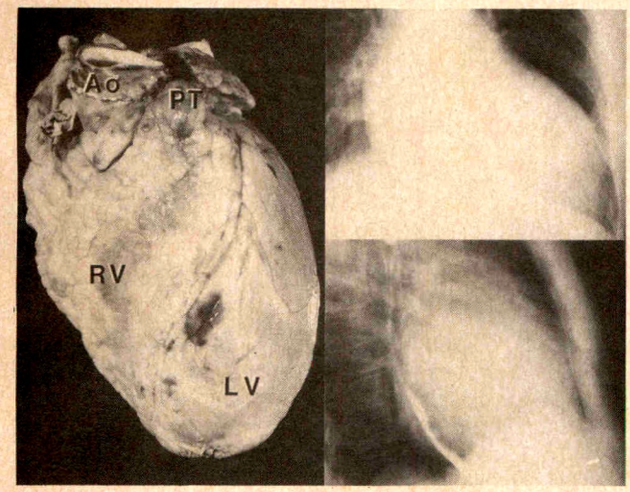

FIGURE 2. Patient 8. **left,** exterior view of heart weighing 1,010 g from a 51-year-old man (A68-8) with chronic aortic regurgitation from syphilis. The enormousness of the heart is apparent from the posteroanterior (**upper right**) and lateral (**lower right**) radiographs. Abbreviations as in Figure 1.

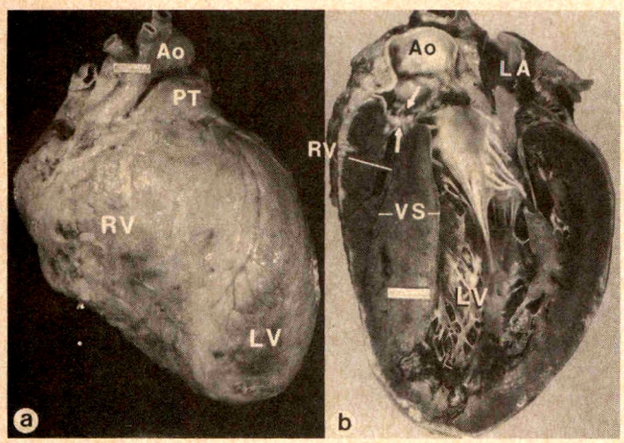

FIGURE 4. Patient 13. Heart from a 29-year-old man (A71-197) with ventricular septal defect (VSD) complicated by aortic regurgitation. He died 1 year after closure of the VSD and replacement of the aortic valve. The aortic regurgitation resulted from prolapse of 1 of the 3 aortic valve cusps. **a,** exterior view of heart. The heart weight (1,360 g) was determined after most of the ascending aorta and pulmonary trunk had been excised. **b,** longitudinal cut of heart. The **arrows** point to the site of the previous VSD. The caged-ball prosthesis has been removed. A thrombus is present in the left ventricular apex. VS = ventricular septum; other abbreviations as in Figure 1.

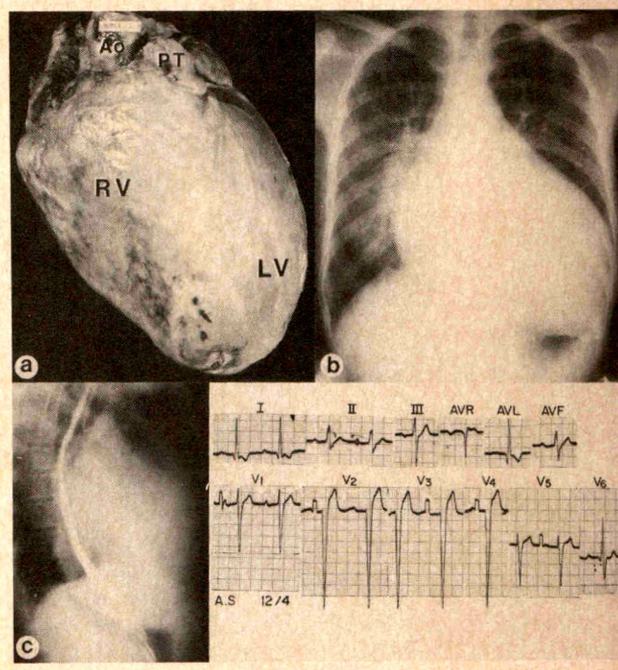

FIGURE 3. Patient 9. Heart weighing 1,040 g (**a**), chest radiographs (**b** and **c**) and electrocardiogram from a 29-year-old man (A68-3) with combined pure aortic and mitral regurgitation of rheumatic origin. Leads V_1 to V_5 are at one-half standard. Abbreviations as in Figure 1.

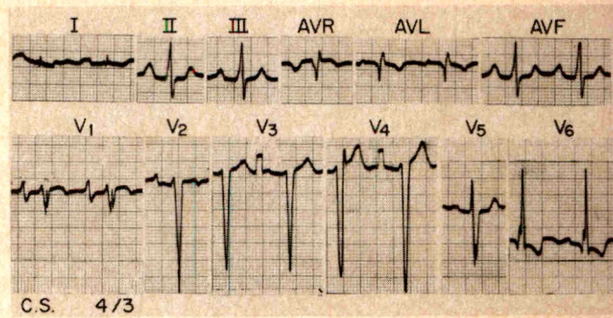

FIGURE 5. Patient 14. Electrocardiogram from a 34-year-old man (A64-92) with aortic regurgitation (AR) complicating ventricular septal defect (VSD). The heart weighed 1,150 g. He had active infective endocarditis at age 21 years and severe aortic regurgitation thereafter. A large perforation was present in the prolapsed aortic valve cusp at the time of closure of the ventricular septal defect and aortic valve replacement 1 year before death. The QRS voltage in the preoperative electrocardiogram is enormous. Leads V_3 and V_4 are at one-half standard.

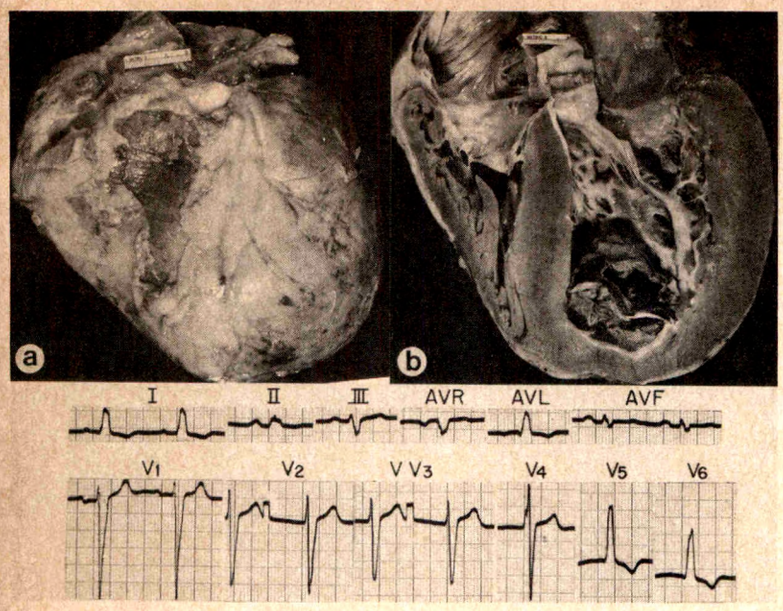

FIGURE 6. Patient 15. Heart and electrocardiogram in a 53-year-old man (A70-54) who developed active infective endocarditis on a congenitally bicuspid aortic valve with severe aortic regurgitation (AR) thereafter. At catheterization before aortic valve replacement, a 20-mm Hg peak systolic pressure gradient was present between left ventricle and aorta and aortic root cineangiogram disclosed 4+/4+ AR. He died 1 year after aortic valve replacement. **a,** exterior view of heart, which weighs 1,100 g. **b,** longitudinal view. The prosthetic aortic valve has been excised. A thrombus is present in the left ventricle. The electrocardiogram shows high QRS voltage in the precordial leads and a strain pattern. Leads V_2 and V_3 are at one-half standard.

listed in Table II. The highest mean 12-lead QRS voltage occurred in lead V_3 (49 mm), next in V_2 (46 mm), next in V_4 (43 mm), and it was lowest in lead aVR (12 mm). The QRS mean voltage in leads V_5 and V_6 were similar (32 and 31 mm).

Various electrocardiographic QRS voltage criteria for left ventricular hypertrophy and the frequency of their occurrence in the 17 patients are summarized in Table III.[6–10] A few criteria have been slightly modified to allow the number designating the upper limit of normal to end in a 0 or a 5 and to allow the elevated value to always be greater than a certain number rather than equal to or greater than a certain number. Of the 18 criteria analyzed, only 1 upper-limit number was evaluated in 3, two values were analyzed in 13, and 4 values in 2. Thus, a total of 37 values were analyzed for the 18 criteria: 36 were measurements in millimeters of QRS voltage and 1 was a ratio.

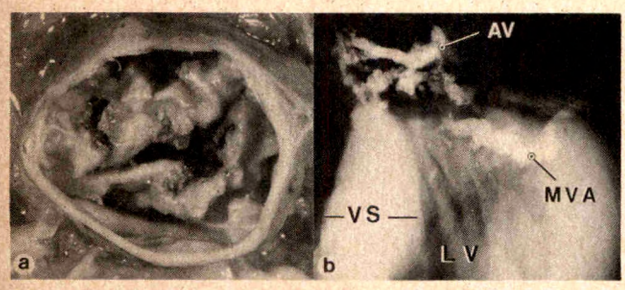

FIGURE 7. Patient 17. Stenotic and heavily calcified, bicuspid aortic valve and calcified mitral valve anulus in a 60-year-old man (A71-14). Congestive heart failure developed about a year before death. Electrocardiogram (not available for reexamination and therefore not included in the analysis of 17) disclosed atrial fibrillation, complete right bundle branch block and Q waves in leads II, III, aVF and V_4 to V_6. This patient had a large anterior wall transmural left ventricular scar. **a,** severely stenotic and mildly incompetent aortic valve from above. **b,** radiograph of heart showing calcium in both aortic valve (AV) and mitral valve anulus (MVA). The mitral valve functioned normally. LV = left ventricular cavity; VS = ventricular septum.

The QRS voltage criterion with the highest positive frequency was the sum of the voltage of the QRS complexes in all 12 leads being more than 175 mm (94%); this total QRS voltage was more than 200 mm in 15 (88%) and more than 250 mm in 13 of the 17 patients (17%).

Several recognized QRS voltage criteria for LV hypertrophy were met in 15 of the 17 patients (88%): (1) sum of the S wave in V_1 or V_2 (larger) plus the R wave in V_5 or V_6 (larger) being >35 mm; (2) sum of the S wave in V_1 or V_2 (larger) plus R in V_6 being >35 mm; and (3) sum of the tallest limb-lead R wave plus the deepest limb-lead S wave being >15 mm.

The S-wave amplitude in lead V_1 ranged from 5 to 50 mm (mean 24); the R-wave amplitude in lead V_5 ranged from 2 to 60 mm (mean 21) and in lead V_6, from 9 to 60 mm (mean 28). The sum of the S wave in lead V_1 and the larger of the R waves in either V_5 or V_6 (Sokolow-Lyon index) ranged from 19 to 92 mm (mean 55), and in 12 patients (71%) it was more than 35 mm. The deepest S wave in leads V_1 to V_3 ranged from 6 to 82 mm (mean 45) and in 14 patients (82%) it was more than 25 mm. The deepest S wave in leads V_1 to V_3 was in lead V_1 in 4 patients (24%), in lead V_2 in 6 patients (35%), and in V_3 in 7 patients (41%). The average S-wave amplitude was higher in lead V_2 than V_1 (40 vs 24 mm).

The largest R-wave amplitude in leads V_4 to V_6 ranged from 9 to 60 mm (mean 30), and in 9 patients (53%) it was more than 25 mm; the largest R wave in V_4 to V_6 was in lead V_5 in 5 patients (29%) and in lead V_6 in 12 patients (71%). The mean height of the R wave was higher in lead V_6 than in V_5 (28 vs 21 mm), and the R wave in V_6 was higher than the R wave in V_5 in 13 patients (76%).

Of the 17 patients with electrocardiograms available for analysis, 13 were in sinus rhythm, 3 had atrial fibrillation and 1 patient had atrioventricular junctional rhythm. The PR interval was prolonged (>0.20 second) in 5 of the 13 patients (38%) with sinus rhythm. The

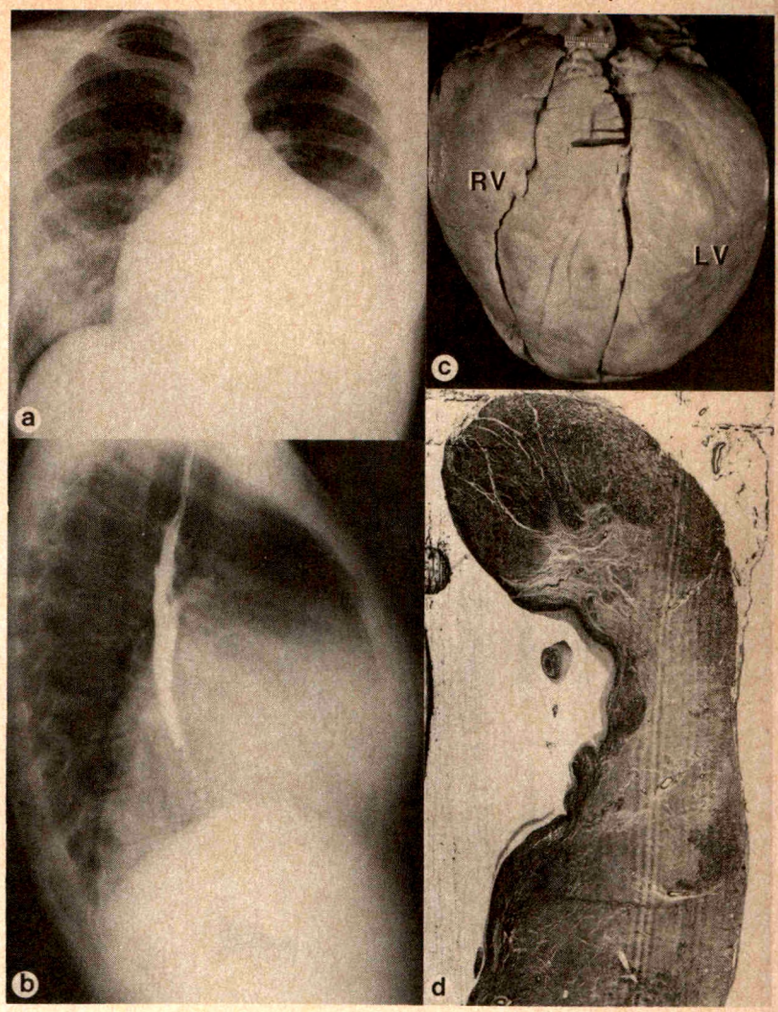

FIGURE 8. Patient 19. **a** and **b,** chest radiographs 4 years before death; **c,** heart weighing 1,250 g; and **d,** longitudinal section of left ventricular free wall showing a healed myocardial infarct in a 20-year-old woman (A72-197) with hypertrophic cardiomyopathy. She weighed 47 kg. The myocardial infarct likely was the result of inability of the normal epicardial coronary arteries to adequately supply the huge mass of myocardium. LV = left ventricle; RV = right ventricle.

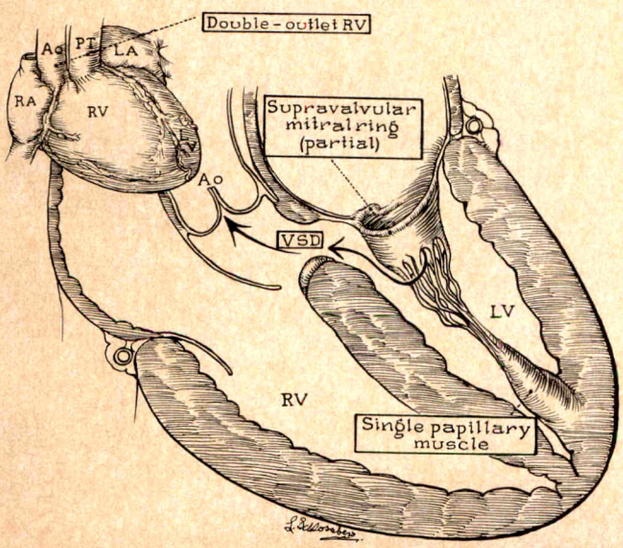

FIGURE 9. Patient 23. Diagram of heart from a 30-year-old man (83-02-106) with congenital mitral stenosis, ventricular septal defect (VSD) and double-outlet right ventricle (RV). The heart weight 1,005 g. Ao = aorta; LA = left atrium; LV = left ventricle; PT = pulmonary trunk; RA = right atrium.

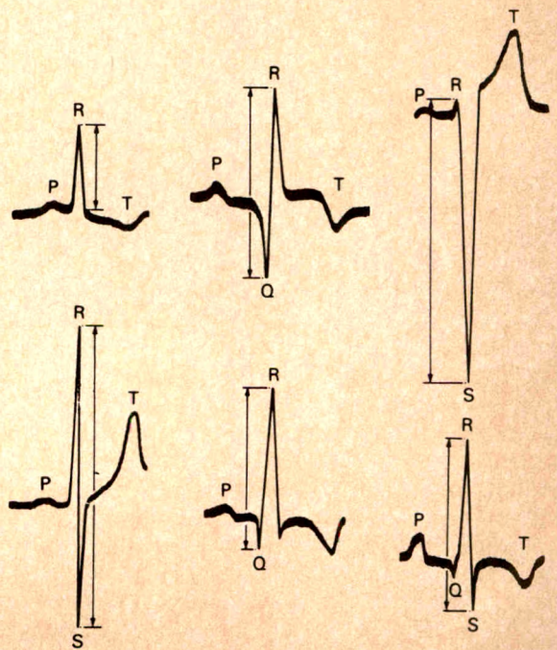

FIGURE 10. Various QRS complexes showing how each was measured.

QRS width was 0.12 second or longer in 12 patients (71%).

Cardiac valve operations were performed in 16 of the 23 patients (70%): isolated aortic valve replacement in 9, simultaneous aortic plus mitral valve replacements in 3, aortic valve replacement plus closure of ventricular septal defect in 2, isolated mitral valve replacement in 1 patient and partial ventricular septotomy-septectomy (for hypertrophic cardiomyopathy) in 1 (patient 22). Eight of the 16 patients died within 90 days (median 3) of operation and the other 8 died 12 to 144 months (mean 49) after operation.

At necropsy, the hearts weighed 1,005 to 1,360 g (mean 1,106); in 15 patients the range was 1,005 to 1,100 g and in 8 it was 1,150 to 1,360 g. The body weight (available in 20 patients) ranged from 47 to 109 kg (mean 74). The percent of body weight contributed by heart weight ranged from 1.1 to 2.7 (mean 1.6) (normal 0.38 to 0.46 [mean 0.40] for women and 0.42 to 0.46 [mean 0.43] for men). Four patients (17%) had congenitally bicuspid aortic valves.

One or more of the 4 major coronary arteries (right, left main, left anterior descending and left circumflex) were narrowed more than 75% in cross-sectional area in 4 of the 23 patients (17%), only 1 of whom had as many as 2 arteries so narrowed. Grossly visible left ventricular scars were found in 4 patients (17%), 2 of whom were among the 4 patients with severe (>75%) coronary narrowing. Two patients (nos. 11 and 12) had small, posterior wall, transmural (> inner one-half of the wall) left ventricular scars. Patient 17 had a large anterior wall scar and a narrowed single coronary artery. Patient 20 had extensive transmural left ventricular scarring with normal extramural coronary arteries; this 20-year-old woman had a 1,250-g heart and she weighed only 103 pounds. We believed that the myocardial ischemia was the result of the myocardial mass "outgrowing" the ability of the coronary bed to perfuse it.

Discussion

The present study includes the largest number of patients heretofore reported with hearts weighing 1,000 g or more. The present study differs from previous ones concerning massive cardiomegaly in that the weights of the hearts, with 2 exceptions, were those recorded by 1 person (WCR) and only after the attachments (great arteries, parietal pericardium, intracardiac clot, and so forth) to the heart had been removed. All previous studies including more than 1 patient with massive cardiomegaly have used heart weights recorded in necropsy protocols, an inaccurate method for obtaining accurate information.[11] Through the years one of us (WCR) has received many hearts originally stated to weigh more than 1,000 g, but after removing the noncardiac attachments the weight was usually less.

The present study demonstrates that there are relatively few conditions that cause the heart to weigh 1,000 g or more. Among our 23 patients, 14 (61%) had *pure "volume" lesions:* isolated AR in 8, AR plus MR in 4, and AR plus VSD in 2. Five patients (22%) had *combined "pressure" and "volume" lesions:* 3 had AS (2 of whom also had considerable AR and 1 [patient 17] of whom had mild AR); 1 patient had mitral stenosis with severe MR; and 1 had mitral stenosis with VSD. Four patients (17%) had *hypertrophic cardiomyopathy*, 2 of whom had peak systolic pressure gradients at rest between left ventricle and aorta. Thus, with the exception of hypertrophic cardiomyopathy and an occasional patient with combined valvular stenosis and regurgitation, it is usually the patient with AR with or without MR or VSD who has a heart that weighs 1,000 g or more.

Several other investigators have observed hearts weighing 1,000 g or more at necropsy. Cabot,[12] in 1926, described 7 men, aged 19 to 52 years (mean 33) whose hearts were recorded as weighing 1,000 to 1,328 g (mean 1150). Although he stated that "chronic pericarditis with mediastinitis produces the largest hearts . . ." all 6 of his patients with "chronic pericarditis and mediastinitis" had valvular heart disease (AR in 4 patients AS in 1 patient and probably both AR and MR in 1). His only patient without "chronic pericarditis and mediastinitis" had syphilitic AR. Golden and Brams[13] described 9 patients (8 men), aged 28 to 57 years (mean 46), with hearts recorded as weighing 1,000 to 1,475 (mean 1,131). The cause of the severe cardiomegaly was AR in 6 (isolated in 5 and associated with MR in 1), combined aortic and mitral valve stenosis in 1 patient and systemic hypertension in 2. Rosenow and Smith[14] reported 3 men, aged 40, 46 and 58 years, with hearts that weighed 1,017, 1,100 and 1,170 g, respectively. Two patients had AS (1 with associated MR) and 1 had systemic hypertension. Strong and Munroe[15] reported 8 patients (7 men), aged 28 to 62 years (mean 43), with hearts recorded as weighing 1,000 to 1,750 g (mean 1,108). The cause of the cardiomegaly was AR in 5 patients, (isolated in 4 and associated with MR in 1), AS in 1 patient and systemic hypertension in 1. Pena[16] reported 15 men, aged 25 to 65 years (mean 49), who had hearts that were recorded as weighing 1,000 to 2,000 g (mean 1,158). The cause of the cardiomegaly was AR in 6 patients (isolated in 4 and associated with MR in 2), isolated MR in 1 patient and systemic hypertension in 8. One of the latter patients also had acromegaly, and his heart weighed 1,525 g. The heart recorded as weighing 2,000 g was in a patient with MR; his blood pressure was 130/70 mm Hg. (We doubt the accuracy of this weight; it is unlikely that the heart can enlarge more than 5 times normal size.) Several investigators in this century have described a single patient in whom the heart weighed 1,000 g or more.[17–24] The cause of the enlargement was AS in 2,[19,22] AR or MR or both in 2,[18,23] cardiac amyloidosis in 1,[24] acromegaly in 1[17] and uncertain cause in 2.[20,21]

Thus, the reports of others cited herein also indicate that valvular heart disease, primarily AR, is the most frequent cause of massive (≥1,000 g) cardiomegaly. In contrast to our study, however, systemic hypertension was mentioned as a cause of massive cardiomegaly. We suspect this cause is unlikely and that more likely the heart was not weighed accurately. Examination by 1 of us (WCR) of hearts of 756 patients with systemic hy-

TABLE IV Frequency of Hearts Weighing 1,000 Grams or More Among Necropsy Patients with Cardiac Disease Studied in the Pathology Branch, National Heart, Lung, and Blood Institute*

	No. of Patients	Number Heart Weight ≥ 1,000 g
Valvular heart disease		
Aortic stenosis (AS)	355	3 (1%)
Mitral stenosis (MS)	216	0
AS + MS	167	1
Aortic regurgitation (AR)	138	8 (6%)
Mitral regurgitation (MR)	122	0
MS + AR	70	0
MR + AR	49	4 (8%)
AS + MR	23	0
Tricuspid stenosis + MS ± AS	29	0
Hypertrophic cardiomyopathy	171	4 (2%)
Ventricular septal defect†	30	3‡
Idiopathic dilated cardiomyopathy	165	0
Amyloid heart disease	57	0
Systemic hypertension	756	0
Acromegaly	9	0
Massive obesity (body weight >176 kg)	12	0
Totals	2369	23

* Excludes coronary heart disease.
† Without associated right ventricular outflow obstruction and age older than 15 years.
‡ Two had associated severe aortic regurgitation and 1 had associated congenital mitral stenosis (parachute mitral valve).
Abbreviations as in Table I.

pertension during life disclosed none weighing 1,000 g or more (Table III). Likewise, among 57 hearts of patients with cardiac amyloidosis extensive enough to cause cardiac dysfunction, none weighed 1,000 g or more (Table IV).[25] Although acromegaly has been reported as causing a human heart to weigh 1,000 g or more,[16,17,26] 1 of us (WCR) has not observed such an occurrence among 9 patients with acromegaly studied at necropsy (Table III).[27] Although in persons of normal weight and without heart disease, heart size is proportional to body weight,[28] such is not the case in patients with massive obesity.[29] Warnes and Roberts[29] studied 12 patients at necropsy whose body weight was more than 176 g (>300 lbs) and their hearts weighed 380 to 990 g (mean 616). No one, to our knowledge, has reported a heart in a human being weighing 1,000 g or more on the basis of massive obesity alone.

Our report is the first to demonstrate hypertrophic cardiomyopathy to be a cause of massive (≥1,000 g) cardiomegaly. Of our 4 patients, 2 were women, the only 2 women among our 23 patients. As a group, the largest hearts among our 23 patients were the 2 with AR plus VSD (mean 1,255 g) and the next largest were the 4 with hypertrophic cardiomyopathy (mean 1,155 g), a weight greater than that of the 8 patients with isolated AR (mean 1,086 g), the 4 patients with AR plus MR (mean 1,079 g), or the 4 with AS (mean 1,100 g). It is not surprising that hypertrophic cardiomyopathy has not been described previously as a cause of massive (≥1000 g) cardiomegaly because the last article on causes of massive cardiomegaly was in 1962 (by Pena[16]) and hypertrophic cardiomyopathy was described only 4 years earlier (1958).[30] Our study also is the first to demonstrate massive cardiomegaly in a patient with VSD. Two of our 3 patients with VSD, however, had AR and the third also had congenital mitral stenosis. It is doubtful that VSD as an isolated anomaly can cause cardiomegaly to the extent that the heart could weigh 1,000 g or more.

The frequency of massive (≥1,000 g) cardiomegaly among certain groups of cardiac patients studied at necropsy by one of us (WCR) is summarized in Table IV. Of the 138 patients with clinically isolated pure AR, 8 (6%) had hearts weighing at least 1,000 g; of the 49 patients with combined pure AR plus MR, 4 (8%) had massive cardiomegaly. Of the 355 patients with AS with or without AR, only 3 (1%) had hearts weighing 1,000 g or more. Of the 171 patients with hypertrophic cardiomyopathy studied at necropsy, 4 (2%) had massive cardiomegaly. None of the 152 patients with idiopathic dilated cardiomyopathy had massive cardiomegaly.[31] Of the hundreds of patients with atherosclerotic coronary heart disease unassociated with another condition and studied at necropsy by one of us (WCR), none had hearts weighing 1,000 g or more.

All but 1 previous study on patients with hearts weighing 1,000 g or more referred to herein were published before 1950 or before 12-lead electrocardiograms became routine (rather than 3 or 6-lead electrocardiograms). The 1 study on huge hearts since 1950 did not describe electrocardiographic findings.[16] Thus, our study is the first to examine 12-lead electrocardiograms in patients in whom the heart weighed 1,000 g or more. Total 12-lead QRS voltage in adults with hearts of normal weight has not been determined but 175 mm (10 mm = 1 mV) would probably be a reasonable upper limit. Of our 17 patients in whom electrocardiograms were available, 16 (94%) had total 12-lead QRS voltage more than 175 mm and in them it ranged from 179 to 601 mm (mean 335); 13 of the 16 patients had total 12-lead QRS voltage more than 250 mm. The largest voltage occurred in 2 patients with hypertrophic car-

diomyopathy (405 and 601 mm), and next in the 2 patients with AR plus VSD (365 and 397 mm). In the 1 patient (no. 18) in whom the total 12-lead QRS voltage was less than 175 mm, the total voltage was 140 mm. This patient had diffuse LV hypokinesia on angiography with an ejection fraction of 23%, insignificant aortic valve disease, severe mitral stenosis and MR, and a large thrombus in the body of the left ventricle (not included in the cardiac weight). Thus, the amount of left ventricle hypertrophy in this patient was much less than in the other 16 patients.

The Sokolow-Lyon index[6] was not a sensitive indicator of left ventricular hypertrophy. The sum of S_{V_1} and R_{V_5} or $_{V_6}$ (larger) was more than 35 mm in only 12 (71%) of the 17 patients, and in these 12 it ranged from 40 to 92 (mean 67); in the 5 patients in whom this index was normal (≤35 mm), it ranged from 19 to 32 (mean 26). The Romhilt-Estes[7] QRS voltage criteria for left ventricular hypertrophy faired worse although it is recognized that non-voltage criteria also were used by these 2 investigators. The patients fulfilling their QRS voltage criteria were as follows: (1) largest R wave in any of the 6 limb leads of 20 mm or more, 6 patients (35%); (2) largest S wave in any of the 6 limb leads of 20 mm or more, 6 patients (35%); (3) largest S wave in leads V_1 to V_3 of 25 mm or more, 14 patients (82%); (4) largest R wave in V_4 to V_6 of 25 mm or more, 10 patients (59%). The criteria for left ventricular hypertrophy examined by Scott et al[8] yielded the following: (1) R wave in lead I and S wave in lead III of more than 25 mm, 7 patients (41%); (2) R wave in V_5 or V_6 of more than 26 mm, 9 patients (53%). (3) R wave plus S wave in any precordial lead of more than 45 mm, 13 patients (76%). Griep[9] and, later, Holt and Spodick[10] used the R_{V_6}:R_{V_5} voltage ratio for diagnosing left ventricular hypertrophy. They found that when the R-wave voltage in lead V_6 was larger than that in lead V_5 that left ventricular hypertrophy was usually present. In 13 of our 17 patients (76%), the R_{V_6}:R_{V_5} ratio was >1. Thus, despite using several ECG criteria for diagnosis of hypertrophy in hearts known to be enormous (≥1,000 g), voltage criteria for left ventricular hypertrophy was present only 35 to 88% of the time (Table III). Measuring total 12-lead QRS voltage appears to be useful in diagnosing left ventricular hypertrophy by electrocardiogram.

Detection of Platelet Deposition at the Site of Peripheral Balloon Angioplasty Using Indium-111 Platelet Scintigraphy

CHRISTOPHER F. POPE, MB ChB, MICHAEL D. EZEKOWITZ, MRCP, PhD,
EILEEN O. SMITH, BS, STANLEY RAPOPORT, MB ChB,
MORTON GLICKMAN, MD, H. DIRK SOSTMAN, MD, and BARRY L. ZARET, MD

Restenosis after balloon angioplasty may be mediated through platelet deposition at the site of arterial dilatation. The purpose of this study was to determine whether platelet deposition at the site of dilatation could be detected using indium-111 platelet scintigraphy. Fifteen patients, aged 60 ± 9 years, with iliac or femoral (n = 12), renal artery (n = 2) or distal aortic (n = 1) stenoses were studied. All patients received intravenous heparin at the time of dilatation. Labeled platelets containing 471 ± 65 μCi indium-111 were injected 0.25 to 4 hours after dilatation and 1 to 24 hours after imaging. In 11 of 12 patients with iliac and femoral dilatations, focal uptake was demonstrated at the angioplasty site. In 4 patients (2 patients with renal, 1 patient with iliofemoral, and 1 with distal aortic stenoses), uptake at the dilatation sites was not detected. This preliminary study indicates that despite intravenous heparin, platelets accumulate at sites of balloon dilatation. Platelet scintigraphy may be useful in predicting sites of future narrowing after angioplasty and may be used to test the efficacy of antiplatelet therapy in retarding restenosis.

(Am J Cardiol 1985;55:495–497)

Percutaneous transluminal balloon angioplasty has become an important therapeutic option for the treatment of both peripheral and coronary atherosclerotic disease. The procedure is relatively nontraumatic and has significant cost advantages compared with surgery.[1] Initial patency rates at 1 month of approximately 86% for iliac and 73% for femoral angioplasty have been reported.[1] However, restenosis after successful dilatation continues to be the major limitation of this procedure. It is estimated that after 1 year, restenosis occurs in 23% of iliac and 44% of femoral dilatations, and that these rates increase to 37% and 71%, respectively, at 5 years.[1] For coronary angioplasty the restenosis rate at 3 to 6 months is estimated to be as high as 36%.[2]

The pathogenesis of restenosis after angioplasty is unclear. Histologic studies at both light and electron microscopic levels demonstrate platelets at sites of dilatation.[3,4] Our hypothesis is that platelets, by virtue of a number of possible mechanisms including vascular spasm, thrombosis and accelerated atherosclerosis, play a major role in promoting restenosis.[5] As a first step in testing this hypothesis, it must be determined whether platelet deposition at the site of dilatation can be reliably demonstrated in vivo in man. To this end, indium-111 platelet scintigraphy was used. This technique is effective in visualizing platelet deposition at sites of atherosclerotic peripheral vascular disease and on the surface of artificial arterial grafts.[6–9] The peripheral circulation, as opposed to the coronary circulation, was chosen for this initial study because the relatively low background blood pool activity and simple geometry provide an ideal anatomic substrate in which to visualize arterial platelet deposition with the scintigraphic technique.

Methods

Patients: All patients selected clinically for peripheral angioplasty were considered eligible for the study. Written informed consent was obtained. Fifteen patients (8 men and 7 women, aged 60 ± 9 years, mean ± standard deviation) were studied. Twelve had femoral or iliac vessel stenoses, 2 had renal artery stenoses, and 1 patient had a lesion in the distal abdominal aorta.

Angioplasty: All arterial punctures were performed through the common femoral artery. Serial dilatations at the stenotic sites were achieved using standard balloon catheters. (Medi-Tech Inc.). Intraarterial heparin (5,000 IU) was administered immediately after the catheter was passed across

the stenosis. After angioplasty, anticoagulant regimens were ordered individually based upon the preference of the physician performing the procedure. No patient received antiplatelet therapy before the procedure. After the procedure 8 patients received intravenous heparin for 8 to 24 hours. An additional patient was administered 40% Rheomacrodex® intravenously at a rate of 500 ml/hour for 3 days. Six patients received long-term therapy (aspirin, 650 mg/day, 4 patients; Persantine®, 75 mg/day and coumadin 5 mg/day, 1 patient; and Persantine alone, 75 mg/day, 1 patient).

Labeling and imaging: Platelets were labeled with 471 ± 61 μCi of indium-111 according to previously described techniques[10–12] and injected 1.2 ± 1.4 hours after dilatation. Ten-minute anterior views of the sites of dilatation and catheter insertion were obtained 13 ± 10 hours after injection of the labeled platelets and subsequently for as long as 5 days. All patients underwent imaging within 24 hours of injection of labeled platelets. Additional images were obtained during the imaging period: 1 image in 5 patients, 2 images in 1 patient, 4 in 3 patients and 5 in 3 patients; in 3 patients only 1 image was obtained. A positive image was defined as an area of increased activity at a site other than the catheter insertion site. A large-field-of-view scintillation camera, fitted with a medium-energy collimator and set with symmetric 20% windows centered on both peaks of indium-111, was used. Patients undergoing renal artery dilatation were imaged in the anterior, posterior and anterior-oblique views. Initial images contained total counts ranging from 169,000 in the pelvis to 54,000 in the thigh. After the catheter puncture site was identified, images were read and then correlated with the angiograms.

Results

In 11 of 12 patients undergoing iliac or femoral angioplasty, areas of intense activity indicating platelet deposition (Fig. 1 and 2), were seen. After 24 hours these remained essentially unchanged. All corresponded to sites of dilatation. In 4 patients uptake at dilatation sites was not detected: in both patients with renal artery stenoses, 1 patient with a distal aortic stenosis and 1 with an external iliac stenosis. The initial platelet images showed increased activity at the puncture site (Fig. 1 and 2) in 12 of 14 patients imaged. The puncture site was not imaged in 1 patient (not in the field of view), and showed no activity in 2 others. Figure 1 demonstrates the value of obtaining sequential images. Initial images obtained 4 hours after dilatation and 3.5 hours after injection of the platelet suspension provided much less convincing evidence of platelet deposition then did the images obtained 20 hours later. Two factors may contribute to this observation: the continual uptake of platelets by the damaged vessel and the diminution of blood pool activity or both these factors working in concert. The images in Figure 2 are from a patient in whom clinically apparent hematoma occurred as a complication of the procedure. This was clearly visualized on the scintigram. Although endothelial damage at the puncture site probably coexisted with the hematoma, it is unlikely that this contributed significantly to the increased activity visualized. Thus, uptake at the puncture site should not automatically be interpreted as representing platelet deposition or thrombosis. In the image in Figure 1 a clinically apparent hematoma was not seen, but the puncture site was clearly visualized. The source of the increased activity may represent endothelial damage. However, clinically silent perivascular extravasation of blood may occur and cannot be excluded as a cause of the increased activity. Figure 2 is an example of inhomogeneous uptake in a patient who underwent dilatation of a long stenosis. There is diffuse

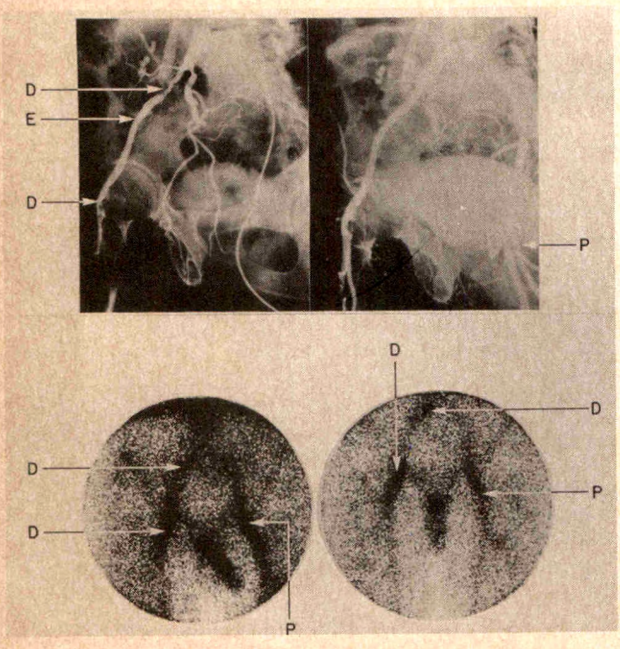

FIGURE 1. Top, pre- (**left**) and post- (**right**) angioplasty angiograms. **Bottom,** corresponding indium-111 images acquired 4 and 24 hours after angioplasty. D = dilatation sites; E = external iliac artery; P = puncture site with associated hematoma. The 24-hour image, with the reduced blood pool activity, clearly shows areas of increased platelet uptake.

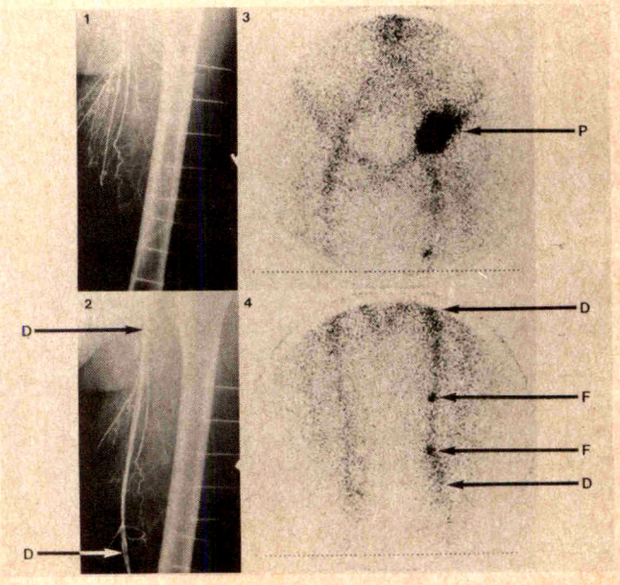

FIGURE 2. Panels 1 and **2,** pre- and postangioplasty angiograms. **Panels 3** and **4,** platelet scintigraphic photos obtained 14 hours after injection. The **arrows** (D) mark the proximal and distal extent of the long stenosis that was dilated. **Panel 4,** diffuse uptake between the 2 markers. In certain areas (F) uptake was more pronounced. A 6 × 6 cm hematoma complicated the procedure. P = puncture site.

uptake along the whole length of the portion of the vessel that was dilated. At sites marked F, increased focal uptake was seen. These areas presumably correspond to the sites of most marked endothelial disruption.

Discussion

After balloon angioplasty, areas of intense indium-111 activity, corresponding to dilatation sites, occur in a high percentage of patients. Because the indium-111 label is not released when labeled platelets undergo adhesion or aggregation,[13] the conclusion that these areas of increased activity represent sites of platelet accumulation is reasonable. Platelet imaging therefore may be used as a marker of early thrombosis or platelet deposition. Platelet deposition at the site of angioplasty in experimental animals has also been documented morphologically.[3] The stimulus for platelet deposition most probably involves exposure of subendothelial collagen (a potent initiator of platelet aggregation) by balloon dilatation and resultant endothelial disruption, fissuring and even medial dissection. Platelet deposition may be a mechanism of accelerating atherosclerosis and restenosis, since platelets release platelet-derived growth factor which by itself can induce myointimal proliferation.[5] Despite the administration of heparin and streptokinase during the angioplasty procedure, and the subsequent administration of antiplatelet and anticoagulant agents during the imaging period, 11 of 15 patients in this study had platelet uptake at sites of dilatation. This is consistent with previous reports demonstrating the lack of effect of heparin, streptokinase and aspirin on platelet adhesion,[14–16] the presumed mechanism of early platelet deposition at sites of dilation. Cunningham et al[17] recently showed that the pretreatment of men undergoing angioplasty with aspirin resulted in the inhibition of uptake of indium-111 labeled platelets. In this study none of the patients were pretreated with aspirin. Those who did receive aspirin did so within 24 hours after angioplasty; no effect was seen. Conflicting results have also been reported in animals. Intravenous aspirin administered 1 hour before angioplasty in the dog had no detectable effect in preventing platelet uptake at the site of dilatation.[18] In contrast, Wu et al[19] reported that small doses of aspirin inhibited platelet uptake in the catheter-injured rabbit aorta, whereas higher doses (150 mg/kg) did not.[19] These differences may reflect species specificity.

The only patient who failed to show platelet uptake at the angioplasty site in the iliac or femoral group had Rheomacrodex® (40% at 500 ml/hour intravenously for 3 days) administered immediately after dilatation. This agent interferes with platelet adhesion.[20] However, until further investigation confirms this effect, this isolated observation should be interpreted with caution. Two patients with renal artery angioplasty demonstrated no focal activity at these sites. Adjacent splenic and hepatic activity may have obscured the activity from the renal artery, and thus it is uncertain whether these patients had true-negative study results. Thus, due to anatomic rather than physiologic considerations, platelet scintigraphy may have limited application in the study of renal angioplasty. This observation was made in another recent study.[21] In the 2 patients in whom uptake at the puncture site was not detected, uptake at the sites of dilatation were similarly absent, suggesting that the platelet preparation was rendered nonphysiologic as a result of cellular damage during labeling. An alternative explanation is that only minimal hematoma occurred at the arteriotomy site in these patients.

Instructions to Authors

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY, that upon submission, they become the property of the Publisher, that the work has not been previously published, and that the data in the manuscript have been reviewed by all authors, who agree with the analysis of the data and the conclusions reached in the manuscript. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced without the written permission of the Publisher. Statements in articles are the responsibility of the authors.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 7960 Old Georgetown Road, Suite 2C, Bethesda, Maryland 20814. The covering letter should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make (for example, the elimination of 1 or more figures or tables or a portion of the text) to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The names of investigators considered unlikely by the authors to give nonbiased reviews of their work may also be submitted.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript, including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page, which should include the title, the full names and academic degrees of the authors, and the institution and city and state or city and country from which the work originated; (2) second title page, with only the title of the article; (3) miniabstract for Table of Contents that includes the full title and names of all authors; (4) abstract; (5) text; (6) references; (7) acknowledgment; (8) figure legends; and (9) tables. Number all pages in the above sequence, beginning with the title page as 1, the abstract as 2, and so on. (Leave the second title page and the miniabstract unnumbered.) Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references), with at least 25-mm (1-inch) margins.

The second title page, on which the names and institution of the authors are omitted, gives the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be solicited. The authors should state which type of review they wish in the covering letter; this request is always honored.

TITLE PAGE, TABLE OF CONTENTS ABSTRACT AND MINIABSTRACT: For the **complete title page,** include the full first or middle and last names of all authors. Provide a short running title of 3 to 6 words. List the institution and address from which the work originated, and provide information about grant support if necessary. Add at the bottom the phrase, "Address for reprints:" followed by full name and address with zip code.

Limit the **abstract** to 250 words and the Table of Contents **miniabstract** to 150 words. List 2 to 6 **key words** for subject indexing at the end of the abstract.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as the Methods, Results and Discussion. **Abbreviations** are permitted, but no more than 4 per manuscript, and then they must be used on every page of the manuscript after they are initially spelled out (followed by the abbreviation) in both abstract and introduction. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence, but try not to begin sentences with numbers. Use symbols for less than (<), greater than (>) and percent (%). Indent for paragraphs except the first one in both abstract and introduction. Consult the Uniform Requirements for Manuscripts Submitted to Biomedical journals, published in *The Annals of Internal Medicine* June 1982;96:766–771, and also the *Stylebook/ Editorial Manual of the American Medical Association* for current usage.

REFERENCES: List all authors, year, volume and inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts, but if they are used, indicate them as such by the abbreviation (abstr) after the title. Do not use periods after authors' initials or after abbreviations for titles of journals. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications, unpublished observations, and manuscripts submitted but not yet accepted for publication do not constitute references.

Journal: Harvey W, Heberden W, Withering W, Stokes W, Murrell W, Einthoven W, Osler W. Anomalies and curiosities of cardiology and of cardiologists. Reflections of famous medical Williams. Am J Cardiol 1984;53:900–915.

Chapter in Book: Cabot RC, White PD, Taussig HB, Levine SA, Wood P, Friedberg CK, Nadas AS, Hurst JW, Braunwald E. How to write cardiologic textbooks. In: Hope JA, ed. A Treatise on Disease of the Heart and Great Vessels. London: Yorke Medical Books, 1984;175–200.

FIGURES: Submit 3 glossy, unmounted prints of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all charts (line drawings). Make decimals, broken lines, and so on, clear enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by title of the article; omit the authors' names so that blinded reviews can be obtained. Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce previously published figures. Limit figures to the number necessary to present the message clearly. Type **figure legends** on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author.

TABLES: Place each table on a separate page, typed double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating numbers of patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate "positive" or "present," a zero (0) for "negative" or "absent," and dash (—) for "no information available" or "not done." Do not use "yes" or "no."

BRIEF REPORTS: Brief Reports must be limited to no more than 3 text pages and 6 references. Longer ones usually will be returned without review. Neither an abstract nor a Table of Contents miniabstract is required for a Brief Report. Subheadings are not used in the body of the Brief Report.

LETTERS (For Publication): The author who submits a letter for consideration for publication should provide a covering letter on his/her own stationery to the Editor-in-Chief stating why the letter should be published. The letter for consideration for publication should be typed, double-spaced, on a separate sheet of plain white paper and limited, with few exceptions, to 2 pages. The original and 2 xerographic copies should be submitted. A title for the letter should be provided at the top of the page. At the end of the letter, the writer's full name and city and state (or country if outside the United States) should be provided. The author's title and institution should not be included. The word "References" does not appear above the list of references in published letters. References should be double-spaced. A letter concerning a particular article in the *Journal* must be received (from authors within the United States) within 2 months of the article's publication.

REPRINTS: Price schedules and order cards for reprints are mailed to the author upon publication of the article. Individual reprints must be obtained through the author.

"Submaximal" Predischarge Exercise Testing After Acute Myocardial Infarction: Who Needs It?

ROBERT F. DeBUSK, MD, and CHARLES A. DENNIS, MD

Submaximal exercise electrocardiography performed before hospital discharge is safe and effective in stratifying prognosis and characterizing functional capacity in patients after acute myocardial infarction (AMI). However, there are reasons to question whether predischarge submaximal exercise electrocardiography represents optimal usage of this technique. Specifically, such testing appears to be inferior to symptom-limited testing 21 days after AMI for distinguishing high-risk from low-risk patients and for providing guidelines for the resumption of customary activities in the first month or two after AMI.

Patients have a substantially higher peak heart rate, blood pressure and workload response to symptom-limited testing at 3 weeks than during earlier testing.[1,4] Even when the peak heart rate at 3 weeks is similar to that achieved *at the same symptom limit* at 2 weeks, the peak workload of the later test exceeds that of the earlier one. This appears to reflect both physiologic and motivational factors. The former include a more complete reversal of bedrest-induced depletion of intravascular volume[5] and a lesser suppression of peak heart rate which results from AMI.[6] The latter include a lesser reluctance of the patient to exert to a true symptom limit as opposed to attainment of a "submaximal" heart rate and a lesser reluctance of the physician to exhort patients to a truly symptom-limited performance. These differences between submaximal and symptom-limited testing take on added significance as the average hospital stay for postinfarction patients decreases to 7 to 10 days or less.

The peak workload elicited by symptom-limited testing at 3 weeks has prognostic value independent of exercise-induced angina and ischemic ST-segment depression.[7,8] A low peak treadmill workload reflects a decrease in left ventricular ejection fraction and reversible ischemic thallium perfusion defects.[8] Both of these abnormalities have prognostic significance in postinfarction patients.[9,10]

We have found that symptom-limited exercise electrocardiography and radionuclide ventriculography performed at 3 weeks have equal prognostic value; symptom-limited exercise thallium myocardial perfusion scintigraphy added little to the combination of these two tests for predicting later cardiac events.[8] In contrast, Gibson et al[10] found that exercise thallium myocardial perfusion scintigraphy has greater prognostic value than exercise electrocardiography when a "submaximal" test protocol was used before hospital discharge. Similarly, Corbett et al[9] found that radionuclide ventriculography performed in conjunction with submaximal exercise has greater prognostic value than submaximal exercise electrocardiography. Leppo et al[11] found that dipyridamole-thallium-201 scintigraphy performed *at rest* 10 to 16 days after AMI is more sensitive than submaximal exercise electrocardiography in predicting future cardiac events.[11]

The distinction between high- and low-risk postinfarction patients can be accomplished with nearly equal predictive accuracy by a variety of methods: symptom-limited exercise electrocardiography or radionuclide ventriculography performed at 3 weeks, submaximal exercise thallium perfusion scintigraphy or radionuclide ventriculography performed before discharge and rest dipyridamole–thallium-201 scintigraphy performed before discharge. However, symptom-limited exercise electrocardiography is superior to all of the other methods for determining the ceiling of functional capacity on which to base recommendations for the resumption of customary physical activities, including occupational work.

Because the prognostic value of symptom-limited exercise electrocardiography performed at 3 weeks rivals that of radionuclide techniques for prognostic stratification[8] and is substantially cheaper, it is reasonable to ask, "Why the rush to perform predischarge exercise testing, with or without radionuclide imaging?"

Proponents of predischarge exercise testing argue that patients may have a reinfarction or die in the 10 to 14 days between hospital discharge and the 21st day. This has not been our experience with over 1,000 men aged 70 years or younger who were considered eligible for symptom-limited 3-week testing because they were free of complications by the 10th hospital day. Of these, 5 (0.5%) had either a reinfarction (3 cases) or died from cardiac causes (2 cases) between the 10th and 21st days after AMI. Offsetting this very small risk is the fact that treadmill-induced deaths after AMI, though infrequent,

From the Cardiology Division, Cardiac Rehabilitation Program, Stanford University School of Medicine, Palo Alto, California. Manuscript received October 9, 1984, accepted October 10, 1984.

Address for reprints: Robert F. DeBusk, MD, Director, Stanford Cardiac Rehabilitation Program, 730 Welch Road, Suite B, Palo Alto, California 94304.

tend to occur before the 14th day after the acute event. The safety argument for predischarge exercise testing thus appears to have little merit in clinically low risk patients who are free of congestive heart failure and unstable angina pectoris.

Another argument advanced for predischarge testing is that such testing is required to provide "clearance" for patients to resume customary activities at home during the 10- to 21-day interval. This argument is equally groundless in patients who are carefully evaluated before hospital discharge. A good prognosis, i.e., low risk of cardiac events from 10 to 14 and 21 days based on clinical characteristics is associated with a well-preserved functional capacity[3]: clinically low risk patients rarely have significant symptomatic limitation during this brief period.

In fact, the widespread policy of submaximal predischarge exercise testing reflects the historical development of the technique and the unique circumstances under which exercise testing is performed in tertiary care university centers, from which most clinical research reports emanate. Early postinfarction treadmill testing was a radical departure from standard clinical practice when the first studies were reported in the U.S.[12,13] Submaximal heart rate–limited protocols were believed safer, a major consideration in the early research.

Later studies adopted the submaximal protocols for these historical reasons and for logistical reasons common to academic medical centers; investigators in these institutions rarely know their AMI patients before admission and are unlikely to see them after hospital discharge. Because of the imperative to examine a "captive" population and the importance of maintaining continuity of a patient database, predischarge submaximal exercise testing has been perpetuated in academic investigations. However, the logistic difficulties encountered in research hospitals should not determine policies in primary care community hospitals where most patients with AMI are treated. Indeed, patients in community hospitals can and do return for testing at 3 weeks. In our experience, more than 95% of patients judged eligible for symptom-limited testing at 3 weeks actually appear for such testing. These patients are treated in community hospitals, primarily in Kaiser-Permanente hospitals within a 30-minute drive from the Stanford Medical Center.

A final reason for the common policy of predischarge exercise testing is the greater convenience it affords the physician. Although this is not a trivial consideration, especially for the physician, it must be weighed against more compelling considerations. For example, DRG reimbursement will exert pressure to defer exercise testing until after hospital discharge. There appears to be little risk in doing so in clinically low-risk patients. Predischarge testing could then be reserved for clinically "high-risk" patients, many of whom will undergo coronary arteriography in preference to exercise testing of *any* sort. Insurance coverage for "early" exercise testing is equally available for inpatient and outpatient testing performed 7 to 35 days after AMI.

These considerations are important in assuring that postinfarction patients receive an optimal evaluation. If logistic considerations preclude outpatient testing, predischarge testing is preferable to none at all. However, a sharp distinction should be drawn between logistic as opposed to medical imperatives for predischarge testing in clinically uncomplicated postinfarction patients.

Billowing, Floppy, Prolapsed or Flail Mitral Valves?

JOHN B. BARLOW, MD, and WENDY A. POCOCK, MB FRCP

More than 2 decades ago the auscultatory features of a late systolic murmur and non-ejection systolic click were shown to originate at the mitral valve.[1] Left ventricular cineangiocardiography confirmed that late systolic murmurs were indicative of mild mitral regurgitation and demonstrated "massive dilatation," "aneurysmal protrusion," "billowing" or "ballooning" of the posterior mitral leaflet.[2,3] Later studies showed that the anterior leaflet was also involved. In 1966, Criley et al[4] clarified the cineangiocardiographic appearances and introduced the term prolapse. Mitral valve prolapse (MVP) is now a widely used term regardless of whether the valve anomaly is anatomically mild, echocardiographically demonstrable, functionally normal or clinically silent. This has contributed to the general confusion, and it is now crucial for the terms billowing, floppy, prolapse and flail to be defined. Such definitions should be based essentially on the functional anatomic, or pathologic, characteristics of the mitral valve mechanism. Auscultatory, echocardiographic, cineangiocardiographic and other clinical features should then be correlated with the probable functional anatomy. It is, after all, the functional anatomy of the mitral valve mechanism that we attempt to assess by all invasive or noninvasive investigations.

We recently expressed the view[5] that the concept propounded by the French cardiac surgeon, Alain Carpentier, defines the essential differences between prolapse and billowing. In this context Carpentier restricts the use of the term prolapse to failure of the leaflet edges to appose normally. Such partial loss of apposition may occur with or without abnormal billowing of the bellies of the leaflets, and mitral regurgitation, albeit mild or even minimal, will inevitably result. This concept of prolapse implies that the valve function is abnormal which is, in fact, both appropriate and correct. Any cardiac valve, provided there is not a hole or a cleft in a leaflet, remains competent while there is sustained coaptation of the leaflet edges. Prevention of apposition may occur if 1 or more leaflets are fibrosed or retracted. If leaflets are normal in size or larger, failure of sustained apposition will result in prolapse. Based on Carpentier's understanding of MVP, we consider that the following terms, which reflect normal and abnormal mitral valve functional anatomy, should clarify much of the current confusion.

The normal mitral leaflets billow slightly, after closure, into the left atrial cavity (Fig. 1A). Exaggeration of this (Fig. 1B), which may range in severity from being marked and diffuse to mild and involving only 1 scallop or even part of a scallop,[6] should be termed a billowing mitral leaflet (BML). This BML may produce a non-ejection click, but mild BML may not be evident on echocardiography or cineangiocardiography. Conversely, BML sufficiently prominent to be demonstrated by these methods of investigation, may not always be detected on auscultation. If the BML progresses, disruption of leaflet edge apposition may ensue and MVP is the result (Fig. 1C). Once there is MVP, mitral regurgitation is inevitable and is reflected clinically by a mitral systolic murmur. Because the BML is more marked it may be demonstrated on echocardiography, but echocardiography, whether M-mode or 2-dimensional, detects systolic displacement of the body of a leaflet and not disengagement of leaflet edge coaptation. If the BML is extreme with very voluminous leaflets and elongated chordae, the term floppy is appropriate. MVP is almost always present with a floppy valve (Fig. 1D) and the mitral regurgitation is often

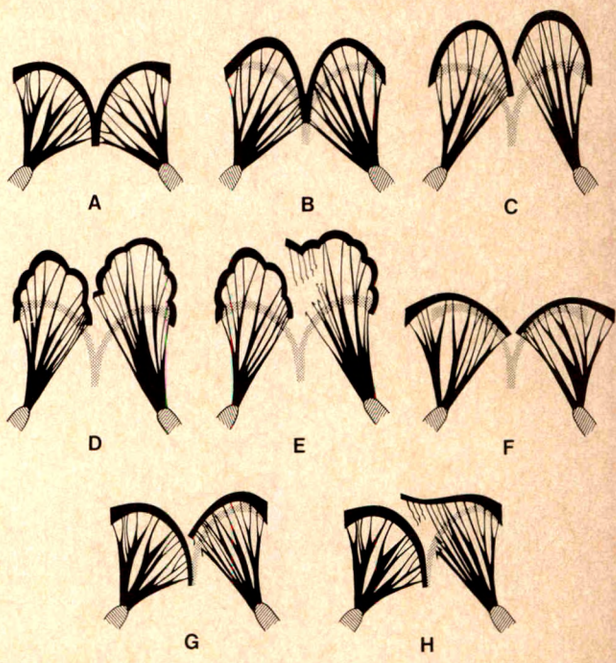

FIGURE 1. Billowing (BML), floppy, prolapsed (MVP) and flail mitral valves. **A,** normal mitral valve showing papillary muscles, chordae tendineae and apposed leaflet edges. **B,** BML; the chordae are lengthened and the voluminous leaflets "billow" into the left atrium. In this and subsequent drawings, the positions of normal leaflets are superimposed with a **stippled** pattern. **C,** BML with MVP; the valve is incompetent. **D,** floppy valve with MVP. **E,** floppy valve and flail leaflet. Marked regurgitation is present. **F,** recent onset anular dilatation causes MVP with minimal BML due to loss of "keystone" effect. **G,** a ruptured minor chorda allows MVP without detectable BML. **H,** flail leaflet with mild BML.

From the Cardiovascular Research Unit, Department of Cardiology, University of the Witwatersrand and the Johannesburg Hospital, Johannesburg, South Africa. Manuscript received September 17, 1984, accepted September 24, 1984.

holosystolic. Echocardiography will readily confirm the floppy leaflets but not the MVP. Progression of the MVP with a floppy valve or with a BML may result in ruptured, or at least grossly elongated, chordae and part of the leaflet will then be flail (Fig. 1E). Mitral regurgitation is now hemodynamically significant and the displacement of the leaflet edge is readily apparent on echocardiography. Thus, although there is overlap and the dividing margins are somewhat ill-defined at present, floppy is the extreme of marked BML and flail that of severe MVP.

Expanding further on Carpentier's concept of "prolapse," MVP may occur with insignificant BML. This could result, for example, from rupture of a minor chord (Fig. 1G) as a result of infective endocarditis on a normal or near-normal mitral valve. Progression to flail, still without BML, could occur after rupture of a major chorda tendinea or with multiple chordal rupture (Fig. 1H). Functionally lengthened chordae due to papillary muscle dysfunction could also cause MVP, sometimes temporarily, without detectable BML. Another mechanism for MVP with only mild BML is recent onset anular dilatation (Fig. 1F). When the "keystone effect"[7] of leaflet edge apposition is diminished, the chordae are subjected to greater tension, and MVP may supervene. In our experience, a principal cause of recent-onset anular dilatation without BML is acute rheumatic carditis. More widely recognized is the combination of a dilated anulus with either marked BML or floppy valve. Anular dilatation, voluminous leaflets and elongated chordae are the characteristic morphologic features[8] of the "floppy valve syndrome,"[9] with or without skeletal manifestations of the Marfan syndrome.

A BML may be a result of a degenerative process[10] (primary BML) or be secondary[11] to other valvular or myocardial pathology (secondary BML). Irrespective of whether protrusion of leaflet scallops into the left atrium can be shown on echocardiography, a BML on its own is a functionally normal valve as far as not allowing incompetence is concerned. Primary BML, whether identified by "echo only"[12] or by hearing an isolated nonejection click,[11] may thus be regarded as a "variant of normal," especially in asymptomatic subjects. When symptoms, electrocardiographic changes, arrhythmias or other features occur, the recognition of a syndrome is justified and for many years we have preferred "billowing mitral leaflet syndrome" to denote that common condition. When a BML is relatively more severe, leaflet edges fail to remain in apposition, mitral regurgitation supervenes and this is MVP. We emphasize that MVP should be detected on auscultation but that mitral regurgitation can only be confirmed, if this is believed necessary, on cineangiocardiography or possibly by Doppler ultrasound. Furthermore, whereas echocardiography may demonstrate the BML, it does not show the MVP until it is very severe or a leaflet flail.

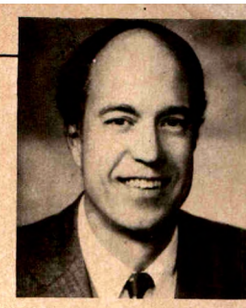
Enticing Real and Potential Cardiovascular Researchers Away from Research



The number of physicians increases each year. Every city in America probably has too many physicians. For the first time in decades, several medical schools in 1984 decreased the number of students admitted to the freshman medical school class.

It appears that there are now too many cardiologists—both adult and pediatric—and cardiovascular surgeons in the USA. Certainly there are too many in the major cities. Competition is getting stiff, but nevertheless the financial reward continues to be good, particularly for those doing invasive procedures. I understand that the cardiologist's fee for coronary angioplasty is usually about $2,500, but that it can be twice that amount. A number of surgeons have told me that their fee for coronary artery bypass surgery usually is about $5,000, with sometimes $2,000 more for the surgical assistant; of course, the anesthesiologist's fee is separate. A cardiac-surgeon friend told me 5 years ago (February 1980) that a cardiac surgeon not making "half a million dollars a year was simply not a good cardiac surgeon." A half million, of course, is derived from 100 bypass operations or an average of only 2 a week. A few valve replacement operations additionally each year take care of the office expenses and malpractice insurance. Although most cardiac surgeons do coronary bypass operations and, therefore, most in private practice receive these high incomes, most cardiologists (however that might be defined[1]) do not do invasive procedures, and furthermore most who do invasive procedures do not do angioplasty. But the noninvasive procedures are also large financial generators in cardiology. Compared with other subspecialties of internal medicine, the income of adult cardiologists is usually substantial. The division of cardiology is the largest generator of income of any subdivision of internal medicine. Thus, both cardiology and cardiovascular surgery are financially rewarding, the most rewarding in these terms of any subspeciality of surgery or any subspeciality of medicine or pediatrics.

Is this high financial reward today in cardiologic practice (either medicine, pediatrics or surgery) too enticing to the creative mind which a decade or so ago would have relished a career in cardiovascular research? I think the answer is yes. Of course, there may be other factors. The young potential investigators observe the difficulty of their senior faculty in obtaining and retaining research grants. They observe the frustration of the senior faculty in trying to do research while managing large clinical responsibilities to generate their incomes. They observe the difficulty of their superiors in getting their research papers published, the near "harrassment" from reviewers and editors, neither of whom "really understand their papers." They observe in surprise the actual energy—both physical and mental—required to create and to generate the data to prove or disprove the idea and the discipline it takes to "package" the product once the results of the investigation are clear.

Although available clinical positions in cardiovascular medicine and surgery are decreasing, positions for cardiovascular researchers are plentiful and good candidates are few[2]. Despite the relative decrease in federal monies for cardiovascular research, pharmaceutical and other private monies are increasing. Money is and will be available to support the good ideas and the good research, but more resourcefulness is now required of the investigator. Cardiovascular disease will not be conquered by doing more coronary angioplasties or bypasses or performing more echocardiograms or nuclear angiograms. But successful research is a selfish and demanding mistress. She never lets up. She disdains fancy cars, elaborate boats, long vacations, too many long weekends, season tickets for this or that, and so on. But, opportunity to utilize one's potential to the fullest is sufficient reward.

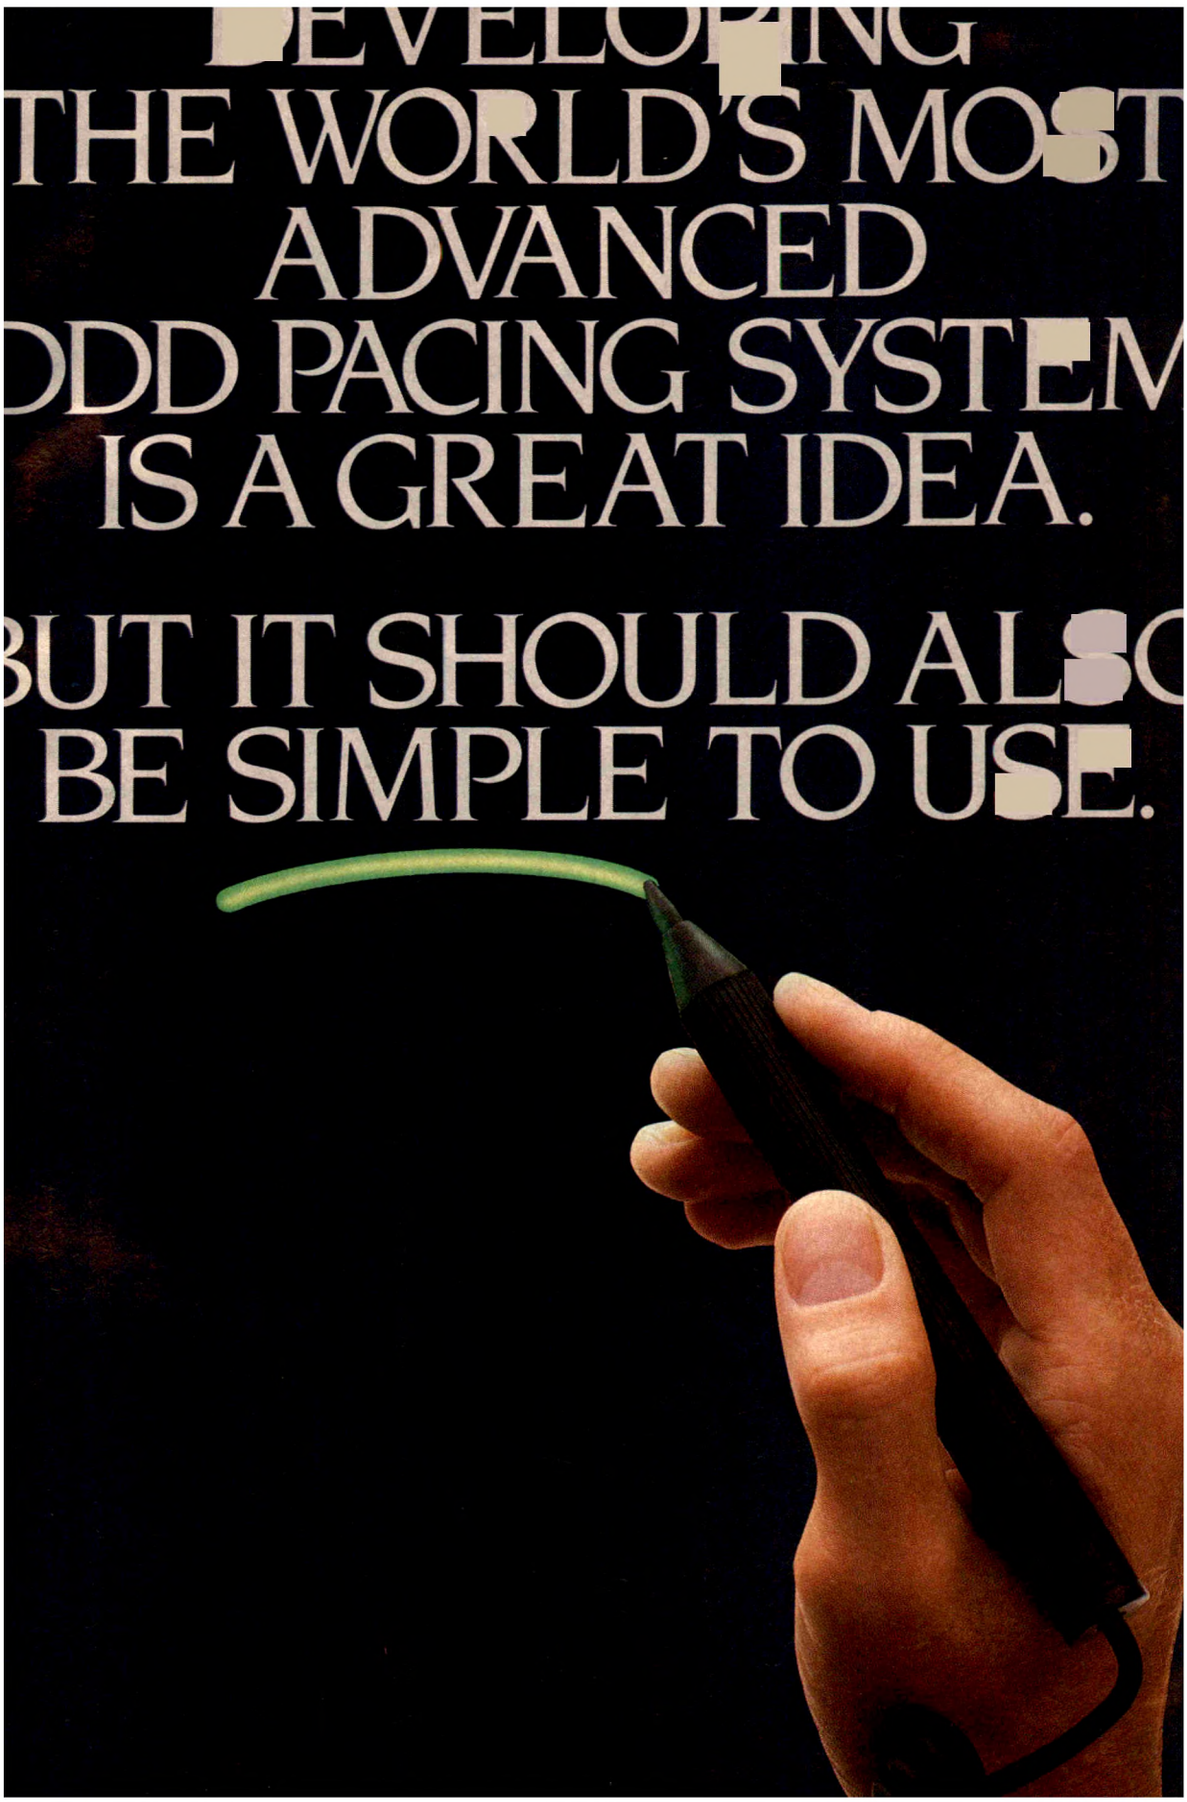
DEVELOPING
THE WORLD'S MOST
ADVANCED
DDD PACING SYSTEM
IS A GREAT IDEA.

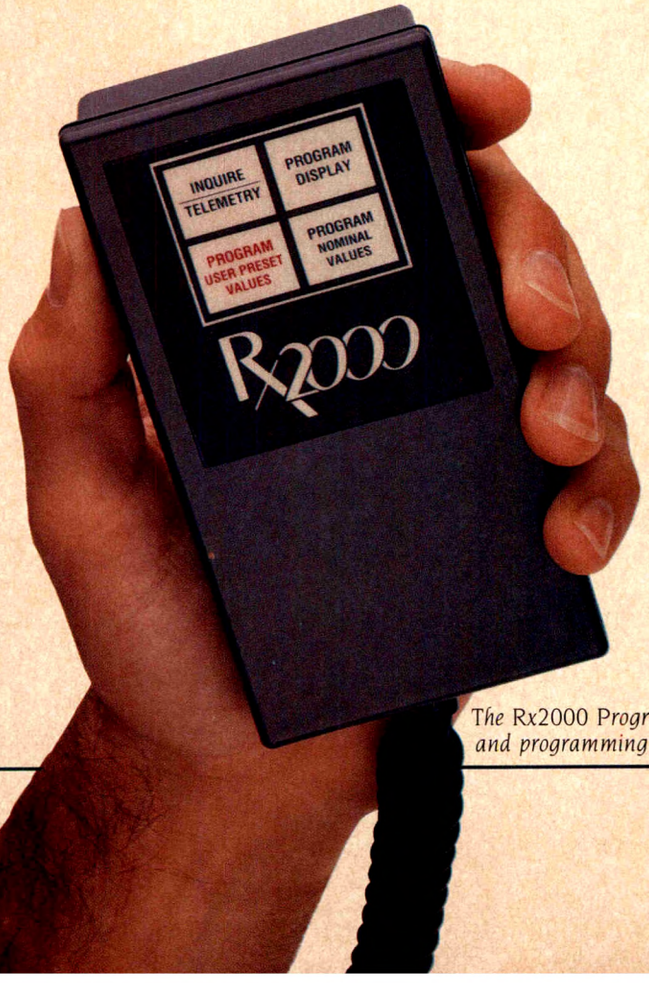
BUT IT SHOULD ALSO
BE SIMPLE TO USE.



INTERMEDICS

COSMOS®

THE EASE OF CONTROL COSMOS OFFERS YOU IS AS UNIQUE AS THE HEART IT SERVES.



The Rx2000 Programmer Wand puts telemetry inquiries and programming functions at your fingertips.

Everything you need is at your fingertips.

From the moment you turn on the Rx2000 programmer, you'll find that everything has been done to make your use of COSMOS simple, fast, effective and safe.

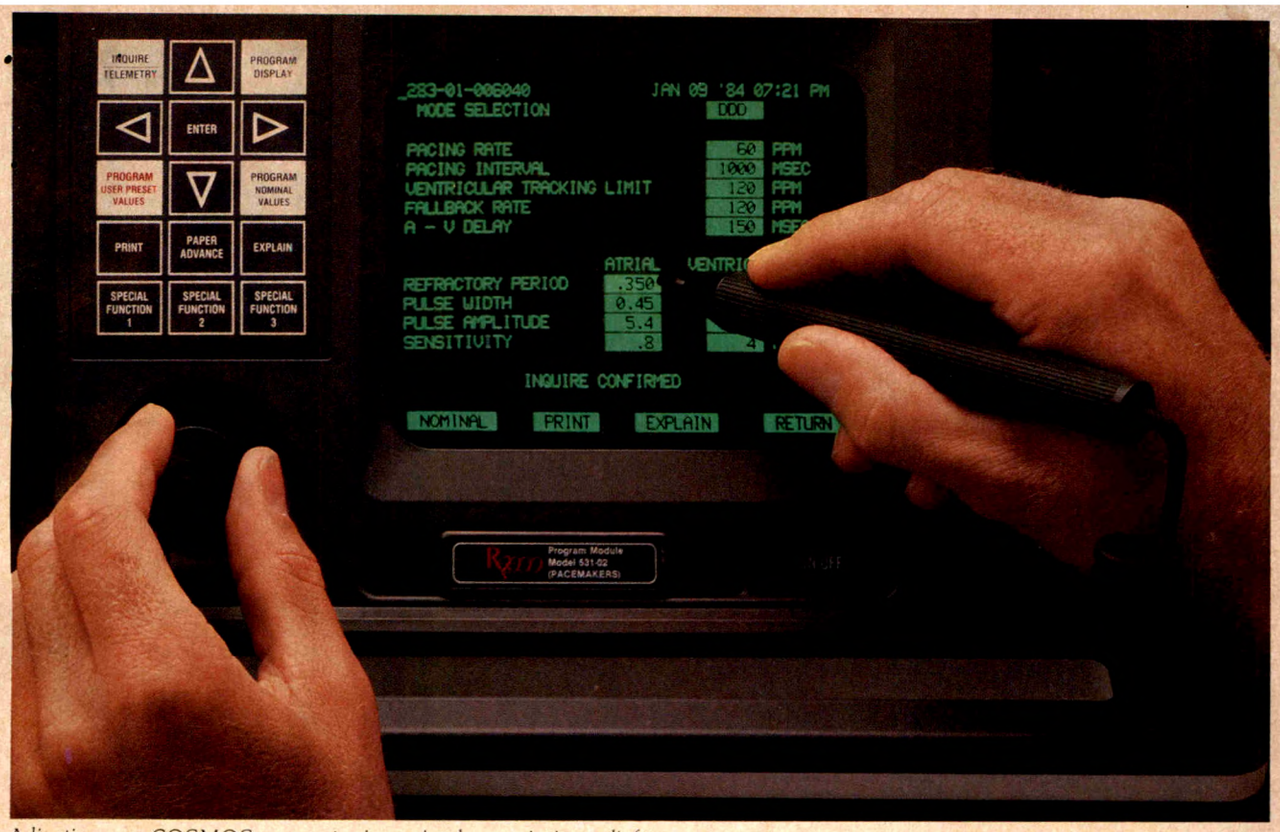
Pick up the light pen and press it to the screen. A full display comes to life telling you every facet of COSMOS, including that the implanted pacer is a COSMOS. Programming the parameters that suit your patient's condition is simply a matter of pressing the light pen to the function you wish to change, for example Refractory Period, and turning the knob on the Rx2000 until the desired value appears next to the title. Programming increments are small, so you can easily set the value that's

The Rx2000 Programmer leads you through the COSMOS programming sequence step-by-step.

right for your patient. If changing one value affects any others, the Rx2000 automatically tells you about it and what to do. And automatic control of PMT and crosstalk inhibition assures your patient's safety.

Need an explanation?

Just press the EXPLAIN key and a full, plain-English text appears on the screen to describe the programming procedure.



Adjusting any COSMOS *parameter is as simple as pointing a light pen and turning a knob.*

Now, with all of the parameters you wish set in place, just press the PROGRAM DISPLAY button. You're done.

If you want to know what the patient's COSMOS has stored in its remarkable memory, select DIAGNOSTIC DATA and it's all on the screen. Press a button and it's printed out for your patient's file.

It's all that simple.

Now you're beginning to understand why leading physicians who have already prescribed COSMOS are making it their choice for DDD pacing.

Getting to know COSMOS is even easier.

Intermedics has a complete range of educational video cassettes that cover everything from implant techniques to advanced DDD pacing concepts. Just ask your Intermedics representative to show you the DDD pacing system as unique as the heart it serves.

Contraindications: For patients exhibiting atrial fibrillation or atrial flutter, careful individual consideration should precede the use of the VDD or DDD mode, since rapid ventricular tracking could ensue.
In cases of chronic atrial fibrillation or atrial flutter, the use of any dual chamber pacing mode may be clinically ineffective.
In patients exhibiting slow retrograde (V-A) conduction, use of the VDD or DDD mode could give rise to pacemaker-mediated tachycardias.

Possible complications: Complications associated with pacemaker implantation include pacemaker-induced arrhythmias; infection; skin erosion; pulse generator migration; hematoma; fluid accumulation; and histotoxic reactions.

Precautions: For the effects of electrical or magnetic interference, defibrillation, diathermy, therapeutic radiation, and industrial or other special environments, see the Physician's Manual accompanying the pulse generator.

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $69.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

Advances in Cardiac Valves
Clinical Perspectives

edited by **Michael E. DeBakey, MD**

0-914316-40-0, November 1983, 274pp., $35.00

This valuable new clinical reference provides a detailed update on many aspects of mechanical heart valve prostheses, including hemodynamics, clinical results, results in children, non-invasive assessments, special indications, and implant techniques. Each topic is presented in an easily understood style and format which facilitate the comprehension of recent developments in heart valve replacement for the busy clinician.

Each chapter is written by internationally respected physicians and medical scientists each of whom is pre-eminent in his field. All of this information has been co-ordinated by Dr. DeBakey to produce a very readable and informative volume on the state-of-the-art of heart valve replacement with mechanical prostheses. No cardiologist, cardiovascular surgeon, internist, or bioengineer can afford *not* to be knowledgeable about the information in this book.

ONE OF A KIND... IN CHF

Avoid any change in the classic Lasix®-digitalis regimen

BRAND OF furosemide

You've titrated to a precise therapeutic response. Now, unless your patient's condition changes, the regimen shouldn't. Because if it does, the sensitive diuretic/digitalis/electrolyte balance could be upset. And the consequences could be serious.

So, once a patient has been stabilized on Lasix® tablets, it's only logical to specify Lasix® by brand name and prevent generic substitution. That's the only way you can be sure your patient will always receive the same brand of furosemide tablets... exactly the same formulation and manufacturing process, with the same excipients and binders... with every single refill. In fact, 9 out of 10 cardiologists do specify Lasix® by brand name, and 2 out of 3 take the extra step to prevent substitution.[1]

Lasix® is the most thoroughly documented drug in its class, with quality so consistent that almost 8 billion tablets have been manufactured without a single product recall.

Reference: 1. National survey of 2960 physicians, including 1502 cardiologists and other physicians subspecializing in cardiology, conducted by Hoechst-Roussel Pharmaceuticals Incorporated, Somerville, New Jersey. August 1982.

Please see following page for brief summary of full prescribing information.

Specify:

LASIX®

BRAND OF FUROSEMIDE 20 mg, 40 mg, 80 mg Tablets

Because there's no substitute for quality

©1985 by Hoechst-Roussel Pharmaceuticals Incorporated

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

How thorough and unbiased is your drug reference?

If it's not the new 16th edition of MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Editor
Gertrude Dittus Gonzales, R.Ph., B.S., Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

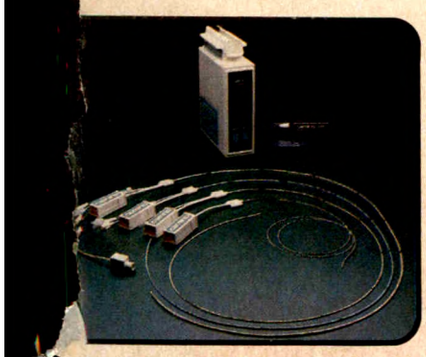
HE ULTIMATE PRESSURE MONITORING SYSTEM
AT YOUR FINGERTIPS



You're looking at the first transducer small enough to fit in a catheter, and economical enough to be disposable.

The Camino system contains the latest developments in fiber optics, metallurgy, and microprocessors. All in a 5 French catheter.

Now you can routinely measure hemodynamic pressures right at the source. No more fluid-filled tubes to degrade the pressure waves or produce artifacts. No more external transducers to buy or calibrate. The result is unsurpasse fidelity and convenience.

For more information, write Camin Laboratories.

Camino System 420 includes digital pressure monitor and choice of transducer-catheters.

In Angina,
When Nitrates Alone
Are Not Enough

Add Calan® TABLETS 80 mg and 120 mg (verapamil HCl)

Now Film Coated and Scored

For an improved lifestyle for your angina patients

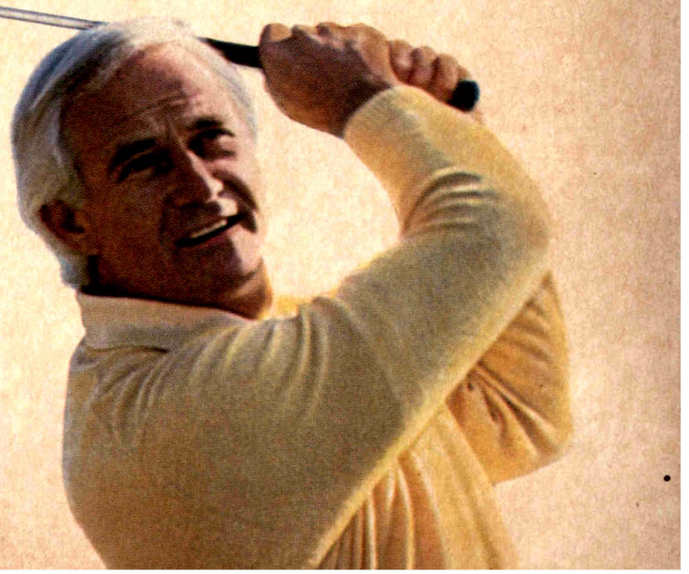
Calan plus nitrates: unique hemodynamic benefits

he addition of Calan improves myocardial perfusion and reduces afterload; the combina-on also produces a reduction in preload. Not all of these important anti-ischemic effects re seen in therapy with nitrates and beta-blockers. That's why you can expect so many patients to do well on Calan plus nitrates.

Calan plus nitrates: patients feel better, can do more

th this therapeutic combination, patients should be able to exercise longer with fewer acks — so they will want to do more. The combination also controls any spasm component, and it can be used without special caution in angina patients who also have asthma, COPD, or diabetes.

ith Calan, serious side effects re rare. The side effect most commonly seen ith Calan is mild constipation. The therapy ntinuation rate for Calan was 94.5% clinical studies.



Please see following page for a brief summary of the complete prescribing information.

SEARLE

4W57T

Calan® TABLETS
80 mg and 120 mg
(verapamil HCl)

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block.

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension, usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Elevations of liver enzymes have been reported. Four cases have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use.

Adverse Reactions: Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, spotty menstruation, ecchymosis, bruising, gynecomastia, and psychotic symptoms. Overall continuation rate was 94.5% in 1,166 patients.

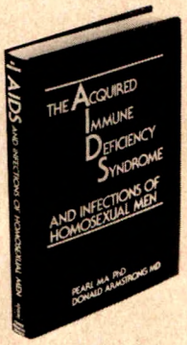
AIDS
An important new book on today's most virulent epidemic



From the Publishers of The American Journal of Medicine, The American Journal of Surgery, and Cutis

Acquire Immune Deficiency Syndrome (AIDS) and Infections of Homosexual Men

edited by **Pearl Ma, PhD,** and **Donald Armstrong, MD** with a foreword by **David J. Sencer, MD,** *Commissioner of Health, New York City; formerly Director, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services*
0-914316-38-9, 442 pages, illus., 1984, $39.50

The first scientific presentation to review all the facts in full

AIDS has become one of the most publicized diseases in modern times. It has produced fear and confusion in the general public and presented a formidable challenge to the medical community. Physicians and scientists have begun work on managing this epidemic, disease control centers continue to search for answers, and the federal government has declared AIDS the number one health priority of the nation. Understanding this disease demands cooperation between many different medical specialties, and papers on this subject have been published in many diverse journals not regularly read by individual specialists. Now, for the first time, two highly distinguished medical experts, Drs. Pearl Ma and Donald Armstrong, have coordinated in one easily accessible volume the complete range of interdisciplinary approaches to this complex disease, with contributions by the most eminent researchers and physicians in disease control and hospital teaching centers throughout the country. Comprehensive coverage is given to the entire spectrum of sexually transmitted diseases, and an additional section on diagnostic perspectives offers never before published material on why this syndrome occurs primarily among homosexual men. For any physician or other health care professional interested in the prevention and cure of this modern epidemic, this book is an indispensable guide to recognizing and treating AIDS and other sexually transmitted diseases.

Table of Contents

• PART I SEXUALLY TRANSMITTED DISEASES — NONDIARRHEAL • PART 2 SEXUALLY TRANSMITTED DISEASES — DIARRHEAL • PART 3 OTHER SEXUALLY TRANSMITTED DISEASES • PART 4 INFECTIOUS AND NEOPLASTIC COMPLICATIONS OF AIDS • PART 5 IMMUNOLOGICAL EVALUATION METHODS AND CONTROLS • PART 6 DIAGNOSTIC PERSPECTIVE

ONE INSIGHT'S WORTH A THOUSAND WORDS.

FRANKLIN'S AFFORDABLE INSIGHT 2000.™ FOR AN ORGANIZED QUANTITATIVE VIEW OF CARDIAC FUNCTIONS.

Now there's a reliable, clinically-priced cardiac analysis system that lets you transform echocardiograms into concise, capsule views of a patient's heart condition.

In minutes, the INSIGHT 2000 provides organized, quantitative reports. Hard numbers that help you judge cardiac reserve, disease progression and response to treatment effectively. And non-invasively.

M-MODE, 2-D, DOPPLER, CINE REVIEW, GLOBAL AND REGIONAL FUNCTIONS.

Your subjective visual review can be enhanced using the INSIGHT 2000's continuous-loop cine review function. Display images in full, split or quad screen formats.

Along with M-mode analysis in less than 120 seconds, special 2-D software provides a wealth of qualitative structure and motion data: lengths, areas, volumes, and ejection fractions.

Plus you'll be able to assess global and regional cardiac function more accurately than ever using the first and only automated wall motion software package to be scientifically validated for reliability and reproducibility.

As well as nine key cardiac output and seventeen mean and peak pressure gradient figures using our optional Doppler software.

EASY TO OPERATE, INTERPRET AND UPGRADE.

The INSIGHT 2000's menu and prompt system cuts technicians' learning curve by teaching with every screen. Once in service, you'll be surprised just how fast a complete work-up and report returns... and just how well it scales your thinking to the evaluation at hand.

Along with updates of your existing software, you have access to completely new cardiographic analysis techniques in the future. Without hardware modification!

BRING INSIGHT INTO YOUR CLINICAL SETTING.

If you believe as we do that the bottom line of diagnostic precision is reliable, reproducible quantitative documentation of cardiac status... there is only one affordable answer.

The analysis system that turns subjective images into hard, objective numbers.

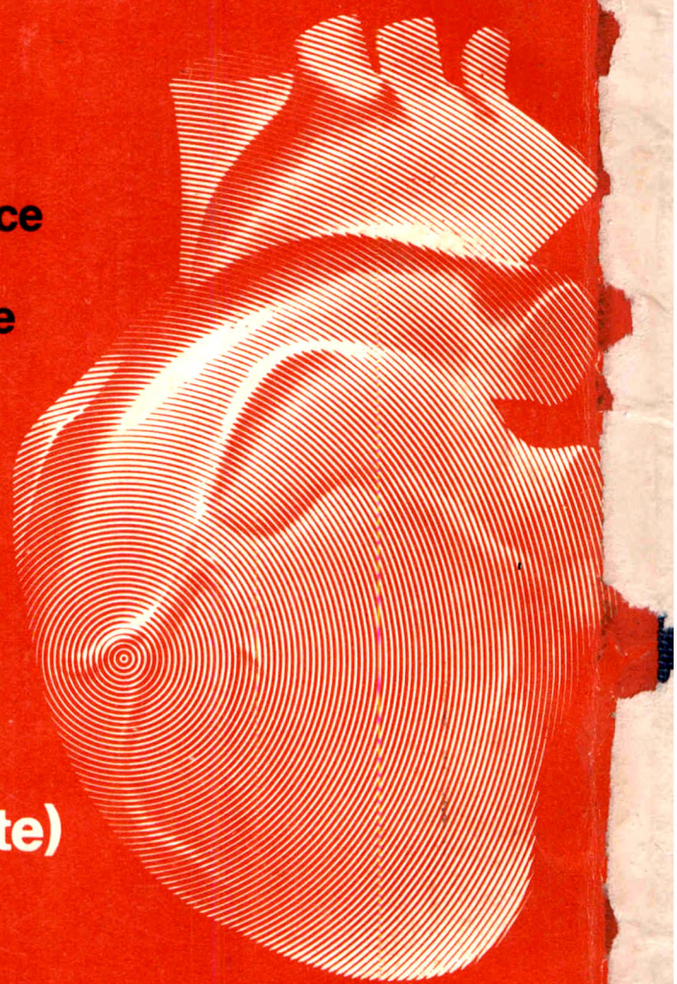
The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.



CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decrease excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digoxin (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: The drug should be used with caution due to excretion of the quinidine in breast milk. ADVERSE REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/or disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTESTINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricular tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMATOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.
